**Dissertation**

Presented to the Faculty of the Graduate School of

The University of Texas at Austin

in Partial Fulfillment

of the Requirements

for the Degree of

**Doctor of Philosophy**

**The University of Texas at Austin**

**August, 2009**

## **Dedication**

To my parents

## **Acknowledgements**

The completion of this dissertation was the result of interactions and discussions with many people. Foremost, I would like to thank my advisor, Dr. Keith P. Johnston, for his guidance and energy throughout my graduate studies. In addition, I would like to thank Dr. Keith J. Stevenson for providing fruitful ideas and discussions which contributed to this dissertation. Collaborating with Dr. Thomas E. Milner was helpful during my first years.

Thanks to the many co-authors who have contributed to the quality of this dissertation. Early guidance from Griffin Smith led to Chapter 2 (along with Jihoon Kim). Prof. Hiroshi Uchida who visited from Japan for one year helped lead to the possibility of Chapter 3, along with contributions from R. Alan May and Ryan D. Williams. Prof. Sheng Dai and Dr. Xiqing Wang contributed to Chapters 4 and 5. Thanks to Dr. Domingo Ferrer, Dr. Steven Swinnea, Dr. Aaron E. Saunders, Andrew T. Heitsch, Jaclyn Wiggins, and Brian Williams for their help in experiments.

I would like to thank the Cockrell School of Engineering at The University of Texas at Austin for their invaluable financial support by giving me the Engineering Doctoral Fellowship, contributed to by anonymous donors.

Special thanks to my group members Gaurav Gupta, Jasmine Tam, and Dan Slanac for insightful discussions and support. Thanks to my lunch group friends (Manas Shah, Landry Khounlavong, Gaurav Goel, and Amogh Prabhu) and to all my friends in Austin (the monkeybarrel) for their friendship.

Exceptional thanks to my parents, family, and Mohini for their support and encouragement.

Supervisor: Keith P. Johnston

The design of nanoparticles in mesoporous supports is explored through synthetic strategies of electrophoretic deposition and electroless deposition with application towards energy storage. Electrophoretic deposition of nanoparticles into a mesoporous thin film is examined using charged nanocrystals in a low-permittivity solvent. To provide a basis for the deposition, the mechanism of particle charging in a low-permittivity solvent was studied. Dispersions of carbon black particles in toluene with an anionic surfactant were characterized using differential-phase optical coherence tomography with close electrode spacing to measure the electrophoretic mobility. The particle charge in concentrated dispersions was found to decrease as a function of increasing surfactant concentration. Partitioning of cations between the surfactant-laden particle surface and micelle cores in the double-layer was found to govern the dynamics of particle charging. Subsequently, charged Au nanocrystals were deposited by electrophoresis within perpendicular mesochannels of a  $\text{TiO}_2$  support. High loadings of 21 wt% Au with good dispersion were achieved within the mesoporous  $\text{TiO}_2$  support using electrophoretic deposition, which would otherwise be inhibited by the weak nanocrystal-support interaction. According to a modified Fokker-Planck equation, the mean penetration depth of a single nanocrystal inside of the perpendicular pores was

found to be dependent on the electric field strength, electrophoretic mobility, pore diameter, nanocrystal size, and local deposition rate constant.

Nanocomposites for electrochemical capacitors were designed via electroless deposition of redox-active  $\text{MnO}_2$  in a high surface area mesoporous carbon support. Disordered mesoporous carbon supports with a pore size of  $\sim 8$  nm were used both in amorphous (AMC) and graphitic (GMC) form, with a  $\sim 1000$ -fold larger conductivity for GMC. High loadings of 30 wt%  $\text{MnO}_2$  were achieved in the AMC in the form of  $\sim 1$  nm thick domains, which were highly dispersed throughout the support. Oxidation of the GMC was necessary to facilitate wetting and deposition of the  $\text{MnO}_2$  precursor in order to achieve high loadings of 35 wt%  $\text{MnO}_2$  with  $\sim 1$  nm thickness. High gravimetric  $\text{MnO}_2$  pseudocapacitances of  $>500 \text{ F/g}_{\text{MnO}_2}$  were achieved at low loadings and low scan rate of 2 mV/s for both carbon supports. However, at high scan rates  $\geq 100 \text{ mV/s}$ , the  $\text{MnO}_2$  pseudocapacitance is twofold larger for  $\text{MnO}_2/\text{GMC}$ , relative to  $\text{MnO}_2/\text{AMC}$ . Sodium ion diffusion throughout both  $\text{MnO}_2/\text{AMC}$  and  $\text{MnO}_2/\text{GMC}$  was shown to be facile. For the GMC versus AMC support, the higher  $\text{MnO}_2$  pseudocapacitance is attributed to the higher electronic conductivity, which facilitates electron transport to the  $\text{MnO}_2$  domains.

## Table of Contents

List of Tables .....	xii
List of Figures .....	xiv
Chapter 1: Introduction .....	1
1.1 Colloidal Particle Charging in Low-Permittivity Media .....	2
1.2 Deposition of Nanoparticles into Mesoporous Supports .....	5
1.3 Deposition of Redox-active Nanoparticles in Mesoporous Carbon for Electrochemical Capacitors .....	11
1.4 Objectives .....	15
1.6 Dissertation Outline .....	16
1.7 References .....	19
Chapter 2: Electrophoretic Mobility of Concentrated Carbon Black Dispersions in Low-Permittivity Solvents by Optical Coherence Tomography .....	31
2.1 Introduction .....	32
2.2 Materials Section .....	35
2.2.1 Materials .....	35
2.2.2 Dispersion Formation .....	35

Figure C.2: Linear dependence of (a) $C_{\text{MnO}_2}$ with $v^{-1/2}$ and (b) $(C_{\text{MnO}_2})^{-1}$ with $v^{1/2}$ to determine the surface contribution to pseudocapacitance compared to the total capacitance.....	173
Figure C.3: (a) Linear dependence of current with $v$ and (b) nonlinear behavior of current with $v^{1/2}$ indicating that the capacitance is based on a surface mechanism and is not diffusion limited. ....	174
Figure D.1: Nitrogen sorption isotherm and pore size distribution data for SMC.	178
Figure D.2: XRD of SMC and 10 wt% $\text{MnO}_2$ /SMC. ....	178
Figure D.3: Nitrogen sorption isotherm and pore size distribution data for OMC.	180
Figure D.4: XRD of OMC and 10 wt% $\text{MnO}_2$ /OMC. ....	180

# Chapter 1

## Introduction

With the demand for energy storage devices increasing, the push for novel materials with high power and energy densities is rising.<sup>1-3</sup> Currently, electrochemical capacitors (ECs) occupy a functional space between batteries and conventional capacitors with high power densities but low energy densities (0.1-10 Wh/kg) and are found in common items such as video recorders, car audio systems, and alarm clock radios.<sup>2, 4, 5</sup> While batteries have larger energy densities (10-100 Wh/kg), they typically have a short life span of ~1000 cycles, whereas ECs can be used for ~500000 cycles with minimal degradation and loss in capacity.<sup>4, 6</sup> Hence, there is intense interest in increasing the energy density of ECs for applications such as hybrid electric vehicle power systems for starting, lighting, and ignition, as well as for load leveling in commercial and industrial equipment.<sup>6-8</sup> Novel nanostructured materials, e.g. redox-active nanoparticles in mesoporous supports, will be crucial in raising the energy density of ECs. The ability to synthesize nanocomposites and understand charging behavior along with ion and electron transport will enable for better materials design to meet the energy demands of the future.

The design strategy to disperse nanoparticles in mesoporous supports is of interest to form nanocomposites with high accessibility of the nanoparticles for heterogeneous catalysis and electrochemical reactions, e.g. in ECs.<sup>9</sup> One method is by electroless deposition of nanoparticles in a mesoporous support. In this process, the support acts as a reducing agent to produce well dispersed nanoparticles, and the deposition can be controlled by varying the reaction time and concentration of reactants. An alternative technique for depositing nanoparticles in mesoporous supports is by electrophoretic deposition,<sup>10-13</sup> where presynthesized nanoparticles in either nonaqueous<sup>14, 15</sup> or aqueous solvents<sup>16, 17</sup> are guided in an electric field for deposition onto a support. Nonaqueous, or low-permittivity, solvents are favorable since many nanoparticle synthesis strategies utilize these solvents,<sup>18</sup> and both positive and negatively charged nanoparticles can be

present simultaneously.<sup>19, 20</sup> High potentials can also be used without the problem of electrolysis or joule heating, which are prevalent in water at low potentials (<5 V).<sup>21, 22</sup> However, the charging mechanism is not fully clear in low-permittivity solvents, and developing an understanding of particle charging in low-permittivity solvents would enable for advancement of electrophoretic deposition of nanoparticles within mesoporous supports. Development of both electroless and electrophoretic deposition is important to form nanocomposites with highly active, accessible nanoparticles.

## 1.1 COLLOIDAL PARTICLE CHARGING IN LOW-PERMITTIVITY MEDIA

An abundance of nanoparticle synthesis techniques are performed in organic solvents to control the particle morphology and size.<sup>18</sup> Insight into the charging of these nanoparticles in nonaqueous solvents would be useful for understanding and developing a wide variety of applications including electrophoretic deposition of nanoparticles into mesoporous supports, ink-jet printing, liquid immersion development,<sup>23, 24</sup> electrophoretic displays,<sup>25, 26</sup> electrostatic lithography,<sup>27</sup> photoelectrophoresis,<sup>28</sup> electrorheological fluids,<sup>29, 30</sup> paints, and petroleum processing.<sup>31, 32</sup> With aqueous systems, colloidal charging and stabilization occur easily with dissociative surface groups or electrolytes playing a dominant role.<sup>32</sup> A fundamental understanding of the charging behavior of colloidal particles in low permittivity solvents would be advantageous for advancing these areas.

Electrostatic stabilization of colloids in low-permittivity solvents with a dielectric constant <5 generally requires additives such as polymers or surfactants to prevent ion paring.<sup>33-43</sup> The thermodynamics of ion separation for a 1:1 electrolyte are given by the Bjerrum length, the ratio between electrostatic interaction energy and thermal energy, as

$$l_B = \frac{e^2}{4\pi\epsilon_r\epsilon_0 k_B T} \quad (1.1)$$

where  $e$  is the elementary charge,  $\epsilon_r$  is the dielectric constant (static permittivity), and  $\epsilon_0$  is the vacuum permittivity. For water, the dielectric constant is high ( $\epsilon_r \approx 80$ ), and  $l_B$  is

quite small at 0.7 nm, which can be provided by water molecules hydrating the ions. However, for nonaqueous systems, the dielectric constant is much lower ( $\epsilon_r \approx 2$ ), and  $l_B$  is much larger at 28 nm. Hence in low-permittivity media, additives such as polymers, crown ethers, or micelles are needed to stabilize the ions in the double-layer (Fig. 1.1). These micelles (or charge carrying entities), which can be  $\sim 5$  nm in size and easily solubilize small ions ( $< 1$  nm), are both positively and negatively charged in dynamic equilibrium with uncharged micelles as given by the charge fluctuation model.<sup>44, 45</sup> The colloid charge is balanced by ion transfer between the micelles in the double layer and colloid surface.

The electrophoretic mobility,  $\mu$ , of colloids is much smaller in low-permittivity media compared to aqueous systems. The electrophoretic mobility,  $\mu$ , is given by

$$\mu = \frac{\zeta \epsilon_r \epsilon_0 f(\kappa a)}{\eta} \quad (1.2)$$

where  $\zeta$  is the zeta potential,  $\kappa a$  is the reduced inverse Debye length, and  $\eta$  is the viscosity of the medium.<sup>46</sup> The value of  $f(\kappa a)$  is determined mainly by the medium and size of the colloids. In aqueous systems  $\kappa a \gg 1$  and  $f(\kappa a) = 1$  (Smoluchowski limit), while for nonaqueous systems  $f(\kappa a) \ll 1$  and  $f(\kappa a) = 2/3$  (Hückel limit). Hence mobilities measured in nonaqueous systems are lower compared to their aqueous counterparts. The mobility is greatly reduced however from the dielectric constant which is  $\sim 40$ -fold lower for organic solvents compared to water. Only a limited number of techniques exist to adequately measure the mobility of particles in nonaqueous media.

One technique used to measure the electrophoretic mobility is using a light microscope and measuring the time it takes for a colloid to travel between fixed electrodes in an electric field, called visual microelectrophoresis. However, this can only be done for dilute dispersions of large particles to adequately identify the particles.<sup>37</sup> Laser Doppler electrophoresis (LDE) can be used to measure mobilities using the frequency shift of light of colloids that are sub-microscopic; however, the mobility of the colloids must be  $> 1 \times 10^{-9} \text{ m}^2/\text{Vs}$ .<sup>47, 48</sup> An extension of LDE is phase analysis light scattering (PALS), which provides for a greater sensitivity to particle motion in an electric field.<sup>49, 50</sup> PALS uses changes in the phase angle to determine the velocity of the

Figure 1.1: Schematic representation of negatively charged particle in the presence of charged and uncharged micelles in the large double-layer with charge transfer between the particle surface and micelles. (Adapted from Ryoo et al.<sup>37</sup>)

particle in an electric field, which is 1000x more sensitive compared to LDE. However, with large electrode spacings (1-4 mm),<sup>51</sup> the small mobilities in low-permittivity media require large potentials,<sup>52-54</sup> which can lead to undesirable reactions<sup>50</sup> and instabilities.<sup>55</sup> Smaller potentials may be used instead with differential-phase optical coherence tomography (DP-OCT), which uses a broadband light source in a backscattering set-up, with close electrode spacing of 0.18 mm.<sup>51, 56</sup> Compared to techniques such as LDE and PALS, more turbid, concentrated colloidal dispersions can be analyzed using DP-OCT with a close electrode spacing since the sample volume is 10<sup>4</sup>-fold smaller.<sup>51</sup>

Recently, TiO<sub>2</sub> particles in toluene with a sodium bis(2-ethyl-1-hexyl)sulfosuccinate (AOT) surfactant were studied using DP-OCT.<sup>39, 51</sup> Particles with different surface chemistries were compared, with a more hydrophilic surface giving a positive charge and a more hydrophobic surface giving a negative charge. The effect of surfactant concentration on the particle charge was also examined, and both surfaces exhibited the same behavior with a decreasing absolute surface charge with increasing surfactant concentration. The charging mechanism was shown to be based on partitioning of ions between the particle surface and surfactant micelles in the double-layer. Examination of other particles would be beneficial to determine if the charging mechanism can be applied on a more global scale.

## **1.2 DEPOSITION OF NANOPARTICLES INTO MESOPOROUS SUPPORTS**

The deposition of nanoparticles in a mesoporous support can be done via multiple strategies. With an understanding of the charging mechanism of colloids in low permittivity solvents, nanocomposites can be formed via electrophoretic deposition of charged nanoparticles into a mesoporous support. Nanocomposites are of great interest for their application as magnetic, photonic, catalytic, sensor, and energy storage materials.<sup>1, 57-59</sup> Nanocrystal incorporation onto a mesoporous support can lead to enhanced optoelectronic and catalytic properties for the composite.<sup>60</sup> Nanocomposite films, composed of a porous TiO<sub>2</sub> support with metal nanocrystals, used for solar cells

can lead to increased light harvesting efficiencies.<sup>61</sup> With control over the size of the metal nanocrystals, e.g. gold, the nanocrystals can act as capacitors for storing electrons for the metal oxide. This results in a shift in the Fermi level of the nanocrystal to equilibrate with the metal oxide leading to better charge separation with smaller nanocrystals having higher efficiencies.<sup>61</sup> Redox-active metal oxide nanoparticles on mesoporous carbon supports can lead to improved gravimetric capacitances.<sup>62, 63</sup> Addition of ~30 wt% MnO<sub>2</sub> nanoparticles on a high surface area carbon support led to a threefold increase in the gravimetric capacitance, relative to the bare carbon support, resulting from the high MnO<sub>2</sub> pseudocapacitance. Hence, the placement of nanoparticles within a mesoporous support to form nanocomposites is important for taking advantage of the nanoparticle properties.

One technique employed to prepare nanocomposite thin films with metal nanoparticles is precursor reduction inside a mesoporous thin film.<sup>57, 64-67</sup> In this technique, a mesoporous film is immersed in a metal ion precursor solution and sufficient time is allowed for the metal ions to diffuse throughout the film. The precursor is then reduced by various means such as heat treatment,<sup>68</sup> electrochemical deposition,<sup>66, 69</sup> or UV exposure.<sup>70</sup> Various nanocrystals such as Au, Pt, and Ag have been synthesized inside thin films with this technique. However, it is difficult to control the nanocrystal morphology and size and uniformity of dispersion; furthermore, the particles may grow until they block the pores as shown in Figure 1.2.

To overcome the difficulties in controlling the nanoparticle composition, size, and dispersion, an alternative approach has been developed to form composites of nanocrystals and mesoporous powders by infusing presynthesized nanocrystals into mesoporous supports.<sup>71-73</sup> The infusion has been driven by sonication<sup>71</sup> or by adding an anti-solvent, supercritical CO<sub>2</sub> to an organic solvent such as toluene.<sup>72, 73</sup> The scCO<sub>2</sub> strengthens the nanocrystal–mesoporous silica interaction leading to higher loadings.<sup>72</sup> This technique provides excellent control over the morphology of the mesoporous support as well as the nanocrystal size, shape, and composition for the purpose of achieving high catalytic activities and stabilities.<sup>71, 73</sup>

Figure 1.2: Illustration of pore blockage and non-uniform metal nanocrystal formation in mesoporous film with precursor reduction technique.

Recently the choice of the binding ligand on the nanocrystals was found to play a crucial role in achieving high loadings in mesoporous powders.<sup>74</sup> Strongly-bound ligands provide a protective covering around the nanocrystal inhibiting strong interactions from forming between the nanocrystal and mesoporous support.<sup>75</sup> Hence, an antisolvent such as scCO<sub>2</sub> was used to infuse nanocrystals inside of the mesoporous materials.<sup>72, 73</sup> Figure 1.3a shows a scanning transmission electron microscope (STEM) image of Ir nanocrystals loaded in mesoporous silica with 1.3 wt% Ir using scCO<sub>2</sub>. The shiny white dots are the nanocrystals, the faint white lines are the pore walls, and the black lines are the pores. Using weakly-bound ligands, the nanocrystal support interaction increases as more of the bare metal is exposed, leading to high loadings through adsorption without the need for an antisolvent. Figure 1.3b shows a STEM image of FePt nanocrystals in mesoporous silica at 8 wt% FePt. Loadings reached as high as 14 wt% FePt in mesoporous silica using the weakly-binding oleic acid/oleylamine ligands.<sup>74</sup>

An alternative approach to design nanocomposite thin films is via electrophoretic deposition of presynthesized nanocrystals. With this technique, nanocrystals with strongly-bound or weakly-bound ligands can be deposited readily. Numerous studies have been performed with monolayer-like deposition on flat substrates such as carbon coated copper grids<sup>76, 77</sup> and ITO/glass.<sup>16, 17</sup> Metal nanocrystals such as Au, Pt, and Ir nanocrystals dispersed in organic solvents have been deposited on disordered 10–15 nm TiO<sub>2</sub> nanoparticles.<sup>15, 78</sup> These metal nanocrystal layers formed by electrophoretic deposition were thicker than those formed by Langmuir Blodgett, self-assembled monolayer, or adsorption techniques.<sup>15</sup> These films also exhibit nanoporosity with aggregation of the deposited gold nanocrystals. CdSe nanocrystals dispersed in an organic solvent, hexane, have also been electrophoretically deposited onto conducting planar substrates of gold to form thick films and line patterns.<sup>14, 79, 80</sup> Electrophoretic deposition produced more uniform films than dry casting or spin casting.

Very few studies report electrophoretic deposition of nanocrystals into mesoporous thin films. The pores of the film should be perpendicular to the substrate and aligned with the electric field (Fig. 1.4).<sup>11, 12</sup> Limmer et al. have infused small nanoclusters inside porous membranes such as track-etched polycarbonate or anodic

Figure 1.3: STEM images of (a) Ir-mesoporous silica composite with 1.3 wt% Ir and (b) FePt-mesoporous silica composite with 8 wt% FePt.

Figure 1.4: Schematic representation of electrophoretic deposition of nanocrystals inside of a mesoporous thin film electrode with pores aligned with electric field.

alumina with pore sizes of 100–200 nm and thicknesses to 10  $\mu\text{m}$ .<sup>13, 81-83</sup> The nanoclusters completely fill the pores of the membranes and were heated to form nanowires. Zhang et al. used electrophoretic deposition to infuse 3 nm CdSe nanocrystals into thin polymer films (30–40 nm) with 15 nm pores.<sup>10</sup> In both of these studies, the pore to particle diameter was over 5; however, further tuning of this ratio to lower values would be important for mesoporous supports of <10 nm pores.

### **1.3 DEPOSITION OF REDOX-ACTIVE NANOPARTICLES IN MESOPOROUS CARBON FOR ELECTROCHEMICAL CAPACITORS**

Nanocomposites of highly dispersed nanoparticles in mesoporous supports are of interest in a variety of practical applications, for example in energy storage. In addition to electrophoretic deposition, this dissertation also examines an electroless deposition technique, wherein the support acts as the reducing agent. The resultant nanocomposites have high surface areas and beneficial properties for electrochemical capacitors. Electrochemical double-layer capacitors (EDLCs), redox pseudocapacitors, ultracapacitors, and supercapacitors are commonly used names for ECs already used prevalently in digital cameras, cell phones, and circuit boards.<sup>4, 8</sup> More recent applications of ECs are in industrial equipment, transportation for starting, acceleration and regenerative braking, and in load leveling for smart grids, e.g., those which contain variable energy sources such as windmills and solar cells.<sup>1, 6, 7</sup> The higher specific power of these devices is ideally suited for the rapid storage and release of energy relative to most batteries, although their specific energy is somewhat lower (Fig. 1.5). However, the gravimetric capacitance and consequently, the energy and power densities of ECs may be increased by improving the design of material architectures to enhance electron transport and ion diffusion.<sup>1, 3</sup>

Electrochemical capacitors may store energy in the electric double-layer and by surface redox (Faradaic) reactions.<sup>1, 84</sup> For EDLCs, the capacitance is directly proportional to the surface area and indirectly proportional to the double-layer thickness,

Figure 1.5: Ragone plot for energy storage and conversion devices. (Adapted from Kotz et al.<sup>4</sup>)

which is typically on the order of  $\sim 1$  nm.<sup>5, 8, 84</sup> For carbon-based EDLCs, the various allotropes, pore structure, surface area, and graphitic content can be manipulated to tailor the conductivity and gravimetric capacitance.<sup>1, 85-98</sup> Activated carbons with surface areas between 500 to 2500 m<sup>2</sup>/g typically have a capacitance between 10 to 35 F/g.<sup>5</sup> The high surface area results predominantly from micropores (<2 nm), with some contribution from mesopores (2-50 nm) and little contribution from the macropores (>50 nm). Micropores are not favorable as they result in reduced ion flow throughout the porous structure.<sup>85</sup> Mesopores are sufficiently large for rapid ion transport<sup>85</sup> and for deposition of nanoparticles with pseudocapacitive behavior.<sup>99</sup> To achieve high capacitance at high scan rates, the electronic conductivity must also be sufficient to compliment rapid ion transport in the mesopores. Graphitic carbons possess carbon atoms arranged in highly ordered, stacked hexagonal rings giving high electrical conductivity.<sup>88, 100</sup> EDLCs composed of highly conductive carbon materials show minimal capacitance fade with increasing scan rates.<sup>98, 101</sup> The ability to design a support with a high surface area mesopores and high electronic conductivity would further enable enhancement in attaining high gravimetric capacitances at high scan rates.

The electric double-layer capacitance may be further increased by either surface functionalization or surface modification with redox-active sites that promote a surface redox pseudocapacitance.<sup>1, 8, 84</sup> Electrode materials for redox supercapacitors are typically conductive polymers or transition metal oxides such as ruthenium or manganese oxide.<sup>1</sup> Ruthenium oxide is an appealing material due to its high pseudocapacitance and high conductivity. Zheng et al. reported specific capacitance values as high as 720 F/g<sub>RuO<sub>2</sub></sub>.<sup>102, 103</sup> Many studies have been completed with different ruthenium oxide nanostructures synthesized such as thin films,<sup>104</sup> nanoparticles,<sup>105</sup> nanoneedles,<sup>106</sup> and nanotubes.<sup>107</sup> However a major deterrent for commercialization of ruthenium oxide is its high cost and low availability.<sup>105</sup> Manganese oxide, a low cost alternative with low toxicity and a high theoretical pseudocapacitance (1370 F/g<sub>MnO<sub>2</sub></sub>),<sup>108</sup> has been studied extensively for ECs.<sup>108-126</sup> High gravimetric pseudocapacitances are typically reported at 700 F/g<sub>MnO<sub>2</sub></sub><sup>114, 126</sup> for thin films on conductive metal planar substrates. An atypically large value of  $\sim 1380$  F/g<sub>MnO<sub>2</sub></sub><sup>109</sup> was reported for MnO<sub>2</sub> porous particles deposited on

conductive platinum foil. However, since  $\text{MnO}_2$  is a mixed conductor, it is difficult to achieve a high pseudocapacitance at high rates, even when it is mixed with conductive agents such as activated carbon.<sup>112</sup> Combining the capacitance and electronic properties of a carbon support with a pseudocapacitive material such as  $\text{MnO}_2$  can lead to higher energy density materials at high rates.

Novel nanocomposite redox pseudocapacitors may be designed by combining conductive, high surface area carbon materials with a redox-active transition metal oxide to increase the gravimetric capacitance. Manganese oxide has been deposited by electrodeposition and electroless deposition on various carbon supports.<sup>62, 63, 99, 127-133</sup> One emerging design strategy is to use mesoporous carbons as scaffolds for  $\text{MnO}_2$  where the porous channels in the carbon support provide high surface area, and the conductive carbon scaffold facilitates electronic conductivity. Small nanoparticles or a conformal coating of  $\text{MnO}_2$ , no thicker than a few nm, may be grown within the mesopores of the highly conductive carbon to improve the utilization of the pseudocapacitive material.<sup>1, 108</sup> For an  $\text{MnO}_2$  loading on the order of 30 wt.%, a uniform coating in 10 nm mesopores would correspond to a film thickness of  $\sim 1$  nm. Thin  $\text{MnO}_2$  films in conductive mesoporous supports with pore sizes of 5-10 nm would be favorable for rapid ion and electron transport to achieve high capacitance. Recent reports of  $\text{MnO}_x$  particles in high surface area carbon supports displayed large gravimetric capacitances.<sup>62, 63, 99, 129, 134</sup> Few studies have evaluated charge storage capacities at high scan rates ( $\geq 100 \text{ mV/s}$ ). At higher scan rates, sloping profiles in the current-potential curves are often observed which suggests kinetic limitations due to sluggish ion and electron transport.<sup>99, 134</sup> Furthermore, typical  $\text{MnO}_2$  modified carbons display substantial capacity fade and low faradaic efficiencies at high scan rates. With a high conductivity support, it would be desirable to tailor the architecture of the pores and the interface between the carbon and  $\text{MnO}_2$  to achieve a high capacitance.

## 1.4 OBJECTIVES

This dissertation studies the design of nanocomposites of nanoparticles in mesoporous supports formed by both electrophoretic deposition and electroless deposition. Electrophoretic deposition is studied first for nanoparticles dispersed in low-permittivity solvents. A fundamental understanding of the charging mechanism of particles in low-permittivity solvents is presented as a basis for the study of electrophoretic deposition. Differential-phase optical coherence tomography is used to measure the electrophoretic mobilities to determine the particle charge. A charging mechanism is described for carbon black particles in a low-permittivity solvent (toluene) containing an anionic surfactant. The effect of surfactant concentration on the particle charge is studied and used to determine the charging mechanism, which is shown in terms of surfactant adsorption on the particle surface and preferential partitioning of cations from micelles in the double-layer to the particle surface. The understanding of particle charging in low-permittivity solvents is subsequently used to guide a study of electrophoretic deposition of nanoparticles into a mesoporous support. Charged gold nanocrystals are deposited into perpendicularly oriented mesochannels of a  $\text{TiO}_2$  thin film. Electrophoretic deposition allows for high loadings to be achieved with presynthesized nanocrystals covered with strongly-bound ligands. Without an electrical field, the deposition would be inhibited by the weak nanocrystal-support interaction. A modified Fokker-Planck equation is used to model the mean penetration depth of a nanocrystal.

Electroless deposition is subsequently investigated to form redox-active metal oxide nanoparticle/mesoporous carbon composites of interest in electrochemical capacitors. Hybrid  $\text{MnO}_2$ /mesoporous carbon nanocomposites with  $\sim 8$  nm pores are synthesized and characterized for  $\text{MnO}_2$  pseudocapacitance and total gravimetric capacitance. High surface area disordered mesoporous carbon supports in both amorphous (AMC) and graphitic (GMC) form are used as sacrificial scaffolds to form  $\text{MnO}_2$  nanoparticles. AMC allows for high loadings to be achieved easily, and the effect

of loading on the pseudocapacitance and total gravimetric capacitance is studied at low and high scan rates. Diffusion of sodium ions throughout the  $\text{MnO}_2/\text{AMC}$  is examined to determine if the pore size is sufficient for ion flow. Graphitization of the mesoporous carbon support at a high heat treatment temperature leads to increased electronic conductivity of the support; however, pretreatment of the GMC via oxidation is required to achieve high loadings of  $\text{MnO}_2$ . The effect of  $\text{MnO}_2$  loadings on capacitance is studied at low and high rates with much higher capacitance values achieved at high rates for the  $\text{MnO}_2/\text{GMC}$ , relative to the  $\text{MnO}_2/\text{AMC}$ . The AMC and GMC composites are compared to determine if ion or electron transport is limiting in achieving a high  $\text{MnO}_2$  pseudocapacitance at high scan rates.

## **1.6 DISSERTATION OUTLINE**

The first half of this dissertation focuses on the use of electrophoretic deposition in low-permittivity media for nanoparticle deposition in a mesoporous support. To provide a basis for the electrophoretic deposition studies, the charging mechanism of particles in low-permittivity solvent is first investigated, which is given in Chapter 2 with carbon black particles in toluene. The carbon black particles are electrostatically charged in toluene in the presence of sodium bis(2-ethyl-1-hexyl)sulfosuccinate (AOT) surfactant. Without surfactant, the carbon black particles settle after  $\sim 1$  hr and show no charge; however with AOT surfactant, the carbon black particles become negatively charged and do not settle. Differential-phase optical coherence tomography (DP-OCT) is used to measure the electrophoretic mobilities of concentrated dispersions of carbon black particles. The close electrode spacing of 0.18 mm, i.e. small sample volume, allows for measurement of up to 1 wt% highly absorbing carbon black. The zeta potential ranged from -24 mV to -12 mV as the AOT concentration was increased from 1 to 100 mM. An electrostatic charging mechanism is discussed in terms of surfactant adsorption on the particle surface and micelles in the double-layer. Preferential partitioning of the hard

sodium cation between the particle and double-layer determines the charge decrease with AOT concentration.

Given the understanding of particle charging in low-permittivity solvents from Chapter 2, Chapter 3 examines electrophoretic deposition of charged gold nanocrystals. The gold nanocrystals dispersed in chloroform are capped with dodecanethiol ligands, and loss of capping ligands is thought to leave an excess positive charge on the nanocrystal. The charged gold nanocrystals were electrophoretically deposited inside of perpendicular mesochannels of a  $\text{TiO}_2$  support. High loadings up to 21 wt% Au were achieved in a short time of only 10 min using electrophoretic deposition compared with only ~5 wt% via adsorption over a 20 hr period. The ligand surface coverage and binding strength on the nanocrystal play a strong role in limiting the interaction between the nanocrystal and  $\text{TiO}_2$  support. With this limitation, electrophoretic deposition provides a driving force to achieve high nanoparticle loadings. The mean penetration depth of a single nanocrystal is modeled using a modified Fokker-Planck equation. The nanocrystal penetration depth inside of the perpendicular pores is found to be dependent on the electric field strength, electrophoretic mobility, pore diameter, nanocrystal size, and local deposition rate constant.

To compliment the study of electrophoretic deposition of presynthesized charged nanoparticles in Chapter 3, electroless deposition is used in Chapter 4 and 5 to form redox-active metal oxide nanoparticles in a mesoporous support. These chapters focus on high surface area mesoporous carbon supports used as sacrificial scaffolds to form hybrid  $\text{MnO}_2$ /carbon nanocomposites for electrochemical capacitors. Chapter 4 centers on using an amorphous mesoporous carbon support with  $\text{MnO}_2$ . High loadings up to 30 wt%  $\text{MnO}_2$  are formed and highly dispersed throughout the ~8 nm pores of the AMC with a  $\text{MnO}_2$  thickness of ~1 nm. For the composites in 1 M  $\text{Na}_2\text{SO}_4$  at 2 mV/s, a low loading of 2 wt%  $\text{MnO}_2$  gives a gravimetric  $\text{MnO}_2$  pseudocapacitance of 560 F/g $_{\text{MnO}_2}$ , whereas 30 wt%  $\text{MnO}_2$  drops to 200 F/g $_{\text{MnO}_2}$ . For 30 wt%  $\text{MnO}_2$  at a high rate of 100 mV/s, the gravimetric  $\text{MnO}_2$  pseudocapacitance drops to 137 F/g $_{\text{MnO}_2}$ . Diffusion of sodium ions is shown to be sufficient throughout the nanocomposite, whereas electron transport is possibly limited due to the amorphous nature of the support.

In an effort to improve the  $\text{MnO}_2$  pseudocapacitance at high scan rates, a graphitic carbon support is used to form  $\text{MnO}_2$ /carbon nanocomposites in Chapter 5. This support has a much higher electronic conductivity ( $\sim 1000\times$ ) compared to the AMC (Chapter 4). The aqueous  $\text{MnO}_2$  precursor does not wet the GMC surface; hence, pretreatment must be done via nitric acid oxidation to increase the oxygen functionalities on the GMC to facilitate  $\text{MnO}_2$  deposition. High loadings of 35 wt %  $\text{MnO}_2$  with  $\sim 1$  nm thick domains were achieved with high dispersion throughout the  $\sim 8$  nm pores of the GMC. In 1 M  $\text{Na}_2\text{SO}_4$  at 2 mV/s, the gravimetric  $\text{MnO}_2$  pseudocapacitance reached 500 F/g $_{\text{MnO}_2}$ . A capacitance fade of only  $\sim 20\%$  over a 100-fold change in scan rate was observed over all  $\text{MnO}_2$  loadings, and a  $\text{MnO}_2$  pseudocapacitance of 310 F/g $_{\text{MnO}_2}$  at 200 mV/s is achieved for 35 wt%  $\text{MnO}_2$ . 35 wt%  $\text{MnO}_2$  also gave a high volumetric capacitance of 400 F/cm $^3$ . The relaxation time constants of  $<1$  s were short for the composites, indicating a high power density. The high graphitic character and disordered mesopores of the GMC facilitates electron and ion transport to the  $\text{MnO}_2$  domains giving high  $\text{MnO}_2$  pseudocapacitances at fast rates of 200 mV/s.

Chapter 6 gives the overall conclusions and recommendations for future work. Supporting information for Chapter 3, 4, and 5 can be found in Appendix A, B, and C, respectively. Appendix D contains experimental details, characterization, and capacitance data on  $\text{MnO}_2$ /carbon composites synthesized using a small pore disordered amorphous mesoporous carbon and an ordered amorphous mesoporous carbon supports.

## Chapter 2

### **Electrophoretic Mobility of Concentrated Carbon Black Dispersions in Low-Permittivity Solvents by Optical Coherence Tomography**

Electrophoretic mobilities of concentrated dispersions of carbon black particles in a low-permittivity solvent were measured using differential-phase optical coherence tomography (DP-OCT). An electrode spacing of only 0.18 mm enables measurement of highly concentrated dispersions up to 1 wt% of highly absorbing carbon black. It also enables high electric fields, at low electric potentials, to measure low electrophoretic mobilities encountered in low-permittivity solvents. The zeta potential ranged from -24 mV to -12 mV as the concentration of surfactant sodium bis(2-ethyl-1-hexyl)sulfosuccinate (AOT) concentration was increased from 1 mM to 100 mM. A mechanism is presented to explain the electrostatic charging of the carbon black particles in terms of the partitioning of the ions between the reverse micelles in the double-layer and the surfactant adsorbed on the particle surface, as the AOT concentration is varied.

---

The contents of this chapter are being prepared for a manuscript.

## 2.1 INTRODUCTION

Carbon black particles are of great importance in applications such as ink-jet printing, electrophoretic displays,<sup>1, 2</sup> paints, and petroleum processing.<sup>3, 4</sup> In these systems, the particles are typically dispersed in a nonaqueous solvent where the electrostatic charge mechanism is not clearly understood. In aqueous systems, colloidal charging and stabilization are more clearly understood in terms of dissociation of surface groups or electrolyte adsorption playing a dominant role.<sup>4</sup> A fundamental understanding of the charging behavior of colloidal particles in low-permittivity media would be beneficial for advancing practical applications.

Electrostatic stabilization of colloids in low-permittivity solvents with a dielectric constant  $<5$  generally requires additives such as polymers or surfactants to separate the ions in the bulk from the surface, that is to prevent ion pairing.<sup>5-16</sup> The thermodynamics of ion separation for a 1:1 electrolyte are given by the Bjerrum length, the ratio between electrostatic interaction energy and thermal energy, as

$$l_B = \frac{e^2}{4\pi\epsilon_r\epsilon_0k_B T} \quad (2.1)$$

where  $e$  is the elementary charge,  $\epsilon_r$  is the dielectric constant (static permittivity),  $\epsilon_0$  is the vacuum permittivity,  $k_B$  is the Boltzmann constant, and  $T$  is the temperature. For water, the dielectric constant is high ( $\epsilon_r = 80$ ), and  $l_B$  is quite small at 0.7 nm. However, for nonaqueous low-permittivity solvents, such as toluene where  $\epsilon_r = 2.4$ , it reaches 24 nm. Here, additives such as polymers, crown ethers, or micelles are needed to prevent ion pairing (Fig. 2.1). The colloid surface is balanced by charge carriers in the double layer in dynamic equilibrium. These micelles can be both positively and negatively charged in their own dynamic equilibrium with uncharged micelles as given by the charge fluctuation model.<sup>17, 18</sup> The charges are easily separated in the double-layer from the surface as the micelles (or charge carrying entities) can be  $\sim 5$  nm in size, which is large enough to solubilize small ions ( $<1$  nm).

Figure 2.1: Schematic of carbon black particle surrounded by reverse micelles showing charge transfer between the particle surface and reverse micelles. (Adapted from Ryoo et al.<sup>9</sup>)

The electrophoretic mobility,  $\mu$ , of particles is much smaller in low-permittivity media compared to aqueous systems, and can thus be difficult to measure. The electrophoretic mobility is given by

$$\mu = (\zeta \epsilon_r \epsilon_0 f(\kappa a)) / \eta \quad (2.2)$$

where  $\zeta$  is the zeta potential,  $\kappa a$  is the reduced inverse Debye length, and  $\eta$  is the viscosity of the solvent.<sup>19</sup> The value of  $f(\kappa a)$  is determined by the medium, electrolyte concentration, and size of the colloids. In aqueous systems where  $\kappa a \gg 1$ ,  $f(\kappa a) = 1$  (Smoluchowski limit), while for nonaqueous systems  $f(\kappa a) \ll 1$  and  $f(\kappa a) = 2/3$  (Hückel limit). Hence mobilities in nonaqueous systems are lower compared to their aqueous counterparts. More importantly, the mobility is greatly reduced by the low dielectric constant of the media which is  $\sim 33$ x lower for toluene compared to water. Only a limited number of techniques exist to adequately measure the mobility of particles in nonaqueous media.

Laser Doppler electrophoresis (LDE) can be used to measure mobilities using the frequency shift of light for particles that are sub-microscopic; however, the mobility of the particles must be  $> 1 \times 10^{-9} \text{ m}^2/\text{Vs}$ .<sup>20, 21</sup> An extension of LDE is phase analysis light scattering (PALS), which provides for greater sensitivity to particle motion in an electric field.<sup>22, 23</sup> In PALS changes in the phase angle are used to determine the velocity of the particle in an electric field, making it 1000x more sensitive compared to LDE. However, given the large electrode spacings (1-4 mm),<sup>24</sup> the small mobilities in nonpolar media require large potentials,<sup>25-27</sup> which can produce undesired chemical reactions<sup>23</sup> and electrohydrodynamic instabilities.<sup>28</sup> Much smaller potentials may be used in differential-phase optical coherence tomography (DP-OCT) given the very narrow electrode spacing of 0.18 mm.<sup>24, 29</sup> Compared to techniques such as LDE and PALS, more turbid, concentrated dispersions can be analyzed with DP-OCT since only a small coherence detection volume is sampled. Previously, it was shown that concentrated dispersions (up to 0.12 wt%) of highly scattering  $\text{TiO}_2$  particles dispersed in AOT-toluene could be easily measured using DP-OCT.<sup>24</sup> Mobilities as low as  $\sim 3 \times 10^{-10} \text{ m}^2/\text{Vs}$  were measured for the  $\sim 200 \text{ nm}$  diameter particles.

Carbon black dispersions with AOT in nonaqueous solvent have been studied with visual microelectrophoresis or LDE.<sup>3, 12-14</sup> In media such as cyclohexane, heptane, benzene, and dodecane, zeta potentials up to -120 mV have been reported. These studies employed large micron-size particles in dilute dispersions. With DP-OCT, smaller particles in concentrated dispersions can be analyzed.

The objectives of this study were to extend the domain of electrophoretic mobility measurement with DP-OCT to concentrated dispersions of highly absorbing particles in a solution of AOT in toluene and to describe the mechanisms that govern the particle electrostatic charging in the low-permittivity solvent. The particle size of carbon black was determined by dynamic light scattering, and the zeta potentials of the negatively charged particles were examined as a function of particle and AOT concentrations. Spectrograms from DP-OCT show the effects of particle concentration on the measurement intensity. The electrostatic charging of the carbon black particles is described in terms of the surfactant adsorption and structure on the particle surface and the preferential partitioning of ions between the adsorbed surfactant layers on the particle surface and the reverse micelles in the large double-layer.

## **2.2 MATERIALS SECTION**

### **2.2.1 Materials**

Carbon black sterling NSX76 was supplied from Cabot Corporation. Surfactant Aerosol-OT (sodium bis(2-ethyl-1-hexyl)sulfosuccinate) and toluene were supplied from Sigma and E-M Science, respectively, and used as received.

### **2.2.2 Dispersion Formation**

The particle dispersions were prepared by mixing surfactant stock solutions with surfactant-free particle stock solutions. The dispersions were shaken vigorously before and after mixing to ensure homogeneity. The particle polarity was determined by using visual microelectrophoresis.

### 2.2.3 Dynamic Light Scattering

The size of carbon black particles in toluene was measured using a Brookhaven Instruments ZetaPlus dynamic light scattering (DLS) apparatus at a scattering angle of 90° and temperature of 25 °C. A dilute particle dispersion (<0.01 wt%) was used to acquire the particle size to avoid multiple scattering. The DLS data was analyzed using a non-negative least-squares (NNLS) method, which is based on the Stokes-Einstein equation for the diffusion coefficient of a sphere,  $D_0 = k_B T / 3\pi\eta d_H$ , where  $\eta$  is the solvent viscosity, and  $d_H$  is the distribution of hydrodynamic diameters.

### 2.2.4 Electrophoresis using Differential-Phase Optical Coherence Tomography

The Doppler shift of light scattered from moving particles was measured using DP-OCT velocimetry.<sup>24</sup> The electrophoresis chamber was a cylindrical void (10 mm diameter and 180  $\mu\text{m}$  thick) in the electrophoresis chamber body, which was cut from a microscope cover slip. The electrodes were ITO-coated glass (Delta Technologies, CG-61IN-S115, 25 mm by 75 mm, 1.1 mm thick, 60-100 nm ITO layer). A 1 Hz frequency of the applied symmetric square wave electric field (10 V amplitude) was high enough to avoid significant accumulation of particles at the electrodes but low enough to provide a substantial duration (0.5 s) of electrophoresis between field reversals. The electric field was low enough also such that stripping of counterions from the particle did not occur to increase the electrophoretic mobility.<sup>4</sup> For  $\text{TiO}_2$  particles in AOT-toluene, a linear increase in electrophoretic mobility was seen with electric field strength (28-56 kV/m), resulting in a constant zeta potential.<sup>11, 24</sup> The electrode separation  $d$  was measured as 180  $\mu\text{m}$  using OCT giving an electric field strength of 56 kV/m for this study.

To perform a measurement, a micropipette was used to dispense at least 20  $\mu\text{L}$  of sample into the electrophoresis chamber. The top electrode was placed and fastened, the electric field was applied, and scans were begun within typically 5 s. For each sample, at least 10 scans were collected, each of duration 2 s. The time between scans was typically 0.5-4 s. Carbon black dispersions that were completely opaque in vials with a 2 cm path length could be studied by DP-OCT in a 180  $\mu\text{m}$  chamber.

For the data analysis, a spectrogram, a three-dimensional plot of intensity of frequencies as a function of time, was generated by short-time discrete Fourier

transform.<sup>24</sup> The spectrogram was calculated for rapid preliminary evaluation of each 2-s scan, as it indicated signal strength and approximate Doppler shift as a function of electric field application time. The average Doppler shift with higher frequency resolution was calculated by a separate discrete Fourier transform.

### 2.3 RESULTS AND DISCUSSION

Dynamic light scattering gives the carbon black particle size distribution (Fig. 2.2). A dilute dispersion in 60 mM AOT-toluene showed a tight particle size distribution centered at ~216 nm with a range of 214-218 nm. The almost uniform size of the particles allows for easier measurements using DP-OCT as diffusional broadening from polydispersity is minimized.<sup>24</sup>

Spectrogram profiles for different concentrations of carbon black dispersions in 60 mM AOT-toluene are shown in Fig. 2.3. With higher particle concentrations, the number of scatters in the coherence detection volume increases, which can result in an increase in the intensity of the spectrogram. While a yellow intensity is satisfactory for identifying particles, a stronger red intensity is more favorable for analyzing the Doppler shift of the particles. At the lowest particle concentration of 0.01 wt% carbon black, the particles produce a yellow intensity in the spectrogram. At 0.1 wt% and 1 wt% carbon black, both yellow and red colors are visible signifying the particles. The DP-OCT technique is highly versatile for analyzing such a wide range in concentration. In our previous study, the highest concentration tested was only 0.12 wt% TiO<sub>2</sub>,<sup>24</sup> nearly an order of magnitude lower. With DP-OCT, the coherence detection volume is small at ~2000  $\mu\text{m}^3$  since the objective diameter is 10  $\mu\text{m}$  and the coherence length is 25  $\mu\text{m}$  for the broadband light source. Other detection volumes are much larger e.g. for LDE it is  $10^7 \mu\text{m}^3$ , which requires dilute dispersions to avoid multiple scattering.<sup>24</sup> Hence with the smaller detection volume, concentrated dispersions can be easily analyzed with DP-OCT when combined with close electrode spacings. The number of carbon black particles

Figure 2.2: Dynamic light scattering size distribution data for dilute dispersion of carbon black in 60 mM AOT-toluene.

Figure 2.3: Spectrogram profiles showing carbon black concentration effect on intensity at 60 mM AOT-toluene: (a) 0.01 wt% , (b) 0.1 wt%, and (c) 1 wt%.

within the volume can be as few as 15 particles at 0.01 wt% or as high as 1500 particles at 1 wt%.

To confirm the particle concentrations had minimal effect on the charging of the particles, the zeta potentials for different carbon black weight fractions in a 60 mM AOT-toluene solution are given in Figure 2.4. The particle polarity was confirmed with visual microelectrophoresis. Although the small particles were not visible, a dark cloud can be seen to move towards the positive electrode between field reversals. The zeta potential was calculated from the electrophoretic mobility (eqn. 2.2) of the carbon black particles measured using DP-OCT, which was measured using the velocity of the particle computed from the beat frequency shift of light under an applied electric field (56 kV/m).<sup>24</sup> For particle concentrations from 0.01 wt% to 1.0 wt% carbon black, the zeta potential was between -13 mV and -12 mV. Therefore, the particle concentrations were low enough compared to the surfactant concentrations such that charging was caused by ion adsorption and not dissociation of ionizable groups on the particle surface.<sup>11, 30</sup> Conversely, high particle concentration dispersions can result in overlap of double-layers, leading to lower zeta potentials.<sup>4, 11</sup> With the relatively constant zeta potential over this particle concentration range, neither ionizable groups nor double layer overlap occurred. For the following experiments, the particle concentration was chosen to be 0.1 wt% since it gave high contrast in spectrograms and fell within the limits tested for particle concentration effects.

Surfactant concentrations were varied from 1 mM to 100 mM AOT in toluene as shown in Fig. 2.5 and Table 2.1 at a particle concentration of 0.1 wt% carbon black. Without AOT surfactant present, neither visual microelectrophoresis nor DP-OCT showed movement of the particles in an electric field. The particles settled after ~1 hr without AOT, but remained dispersed for >24 hrs with AOT. In contrast, a high zeta potential of -24 mV or electrophoretic mobility of  $-5.8 \times 10^{-10} \text{ m}^2/\text{Vs}$  was measured at the lowest surfactant concentration of 1 mM AOT. At the highest concentration of 100 mM AOT, the zeta potential decreased to -12 mV ( $-2.9 \times 10^{-10} \text{ m}^2/\text{Vs}$ ). A similar type of trend of decreasing particle charge has been observed for TiO<sub>2</sub> particles dispersed in AOT-toluene.<sup>11</sup>

Figure 2.5: AOT surfactant concentration effect on zeta potential at 0.1 wt% carbon black in toluene.

Table 2.1. AOT surfactant concentration effect on 0.1 wt% carbon black particle charge in toluene.

AOT conc. (mM)	Electrophoretic mobility ( $10^{-10}$ ) ( $\text{m}^2/\text{Vs}$ )	Elementary charges/particle	Zeta potential (mV)
1	-5.8	4.3	-24
3	-4.9	3.7	-21
10	-3.6	2.7	-15
30	-4.2	3.1	-17
60	-3.0	2.2	-13
100	-2.9	2.2	-12

Zeta potentials in the current study were much lower compared to previous reports (-25 to -115 mV) for carbon black dispersions in AOT-organic solvent systems.<sup>12-14</sup> For a carbon black dispersion in AOT-benzene, the zeta potential decreased from -115 mV to -70 mV for a range of 5-80 mM AOT.<sup>12</sup> The amount of water present in the system also plays a role in the absolute value of the particle zeta potential. For carbon black particles dispersed in 20 mM AOT-cyclohexane, the zeta potential decreased from -60 mV to -20 mV with increasing water content from 5-200 mM H<sub>2</sub>O.<sup>13</sup> For the samples in the current study, no excess drying steps were taken. The amount of water is expected to be similar to the amounts in our previous study with 10-30 mM H<sub>2</sub>O for 0-90 mM AOT.<sup>11</sup> Slightly more water is possibly introduced from the carbon black particles. Since the carbon black particles are amorphous and contain oxygen functional groups on the surface,<sup>31</sup> some amount of pre-adsorbed water is perhaps present. The lower zeta potentials of the carbon black particles with AOT herein also were too low to provide for complete electrostatic stabilization. An absolute zeta potential of ~30 mV<sup>32</sup> is needed to electrostatically stabilize the particles; hence, the AOT also provides steric stabilization to contribute in keeping the carbon particles well dispersed.

The adsorption of the bulky sulfosuccinate hydrocarbon chains takes place with a decreasing areal footprint with increasing AOT concentration. For graphite particles dispersed in cyclohexane with AOT, the AOT adsorption density increased from 0.5  $\mu\text{mol}/\text{m}^2$  at 1 mM AOT to 4.8  $\mu\text{mol}/\text{m}^2$  at 30 mM AOT.<sup>33</sup> Herein, at 0.1 wt% carbon black particles of 216 nm diameter, these adsorption densities would correlate to AOT concentrations of 0.005 mM and 0.05 mM AOT adsorbed onto the particle surface, which is much less compared to the bulk AOT concentrations of 1 mM and 30 mM AOT. Hence, the particle surface is already covered with AOT molecules at low surfactant concentrations as given in Fig. 2.6a, but with a large areal footprint (~330 Å<sup>2</sup>). At high AOT concentrations (Fig. 2.6b), the areal footprint is small (~35 Å<sup>2</sup>) with AOT molecules more closely packed on the particle surface.

A proposed mechanism for electrostatic charging of the carbon black particles is given in Figure 2.6 based on our previous study.<sup>11</sup> The soft sulfosuccinate hydrocarbon chains of AOT preferentially adsorb on the particle surface relative to the hard cations.

At low concentrations, the particle surface is loosely covered with AOT molecules<sup>11, 33</sup> along with reverse micelles formed in the bulk (Fig. 2.6a). Water (>10 mM) is present in the system at low AOT concentrations and gives rise to a high  $W_o$  (water to surfactant ratio) and swollen micelles in the double-layer.<sup>11</sup> The carbon black has a negative charge formed from the sulfosuccinate anion with the hard sodium cation favoring the hydrated swollen reverse micelle cores in the thick double-layer. The net negative charge of the carbon particle, which has only  $\sim 4$  elementary charges per particle, is balanced in the double layer by positive charges from the sodium cations in the hydrated reverse micelles. The double-layer is also in dynamic equilibrium with both positive and negative charges as given by the charge fluctuation model.<sup>17, 18</sup> With increasing surfactant concentration, the carbon black particle surface becomes covered by closely-packed sulfosuccinate ions and reverse micelle type entities form on the particle surface (Fig. 2.6b).<sup>11, 16, 33</sup> The number of reverse micelles in the double-layer increases much more than the water amount (>30 mM)<sup>11</sup> causing the  $W_o$  to decrease, and the water cores shrink in the reverse micelles. With the increase in the reverse micelles on the particle surface, and thus the hydrophilic domains, sodium ions migrate towards the particle and reduce the charge to  $\sim 2$  elementary charges per particle. This change in sodium ion partitioning results in a decrease in the zeta potential as seen in Fig. 2.5. Hydrophobic  $\text{TiO}_2$  particles dispersed in AOT-toluene followed a similar charging mechanism as described by Smith et al.<sup>11</sup>

## 2.4 CONCLUSIONS

The spectrogram intensities are sufficient in DP-OCT to determine electrophoretic mobilities even with highly absorbing carbon black particles in concentrated dispersions at 1 wt%. An advantage of the narrow electrode spacings (0.18 mm) in DP-OCT is that higher strength electric fields, needed to measure small mobilities accurately, may be realized at lower absolute potentials to reduce electrohydrodynamic instabilities and electrode reactions.<sup>24</sup> Zeta potentials in the range of -24 mV to -12 mV were measured

for surfactant concentrations from 1 mM to 100 mM AOT-toluene. The electrostatic charge on the particles depends on the preferential partitioning of ions between the reverse micelles in the double-layer and the particle surface. At low concentrations the cations prefer the reverse micelles more strongly resulting in more negative zeta potentials, whereas at high concentrations the cations partition towards the particle surface and lower the magnitude of the charge. The ability to measure electrophoretic mobilities with DP-OCT with low electrical potentials and over a wide range of particle concentrations will be beneficial for further understanding the complex charging mechanisms for particles in low-permittivity solvents.

## Chapter 3

### **Electrophoretic Deposition of Au Nanocrystals inside Perpendicular Mesochannels of TiO<sub>2</sub>**

Au nanocrystals stabilized by dodecanethiol were deposited into 100 to 150 nm thick TiO<sub>2</sub> films with evenly spaced perpendicular nanopillars and mesochannels on the order of 10 nm supported on conducting ITO/glass electrodes. Electrophoretic deposition was used to enhance nanocrystal deposition within the mesoporous TiO<sub>2</sub> film. X-ray photoelectron spectroscopy (XPS), scanning electron microscopy (SEM) with energy dispersive X-ray (EDX), UV–vis spectroscopy, variable angle spectroscopic ellipsometry (VASE), and scanning surface potential microscopy (SSPM) were used to characterize the resulting Au nanocrystal/TiO<sub>2</sub> composites. Au nanocrystal loadings reached 21 wt% and were not kinetically limited at 10 min, relative to depositions performed for 20 hours. Both VASE measurements of the anisotropy of the imaginary refractive index,  $k$ , and XPS depth profiling studies indicate that Au nanocrystals are dispersed within the vertically aligned mesopores and distributed throughout the film. The mean penetration depth of a single nanocrystal penetrating inside the film is described with a model in terms of the electric field and a local deposition rate constant, which is influenced by ligand binding and architecture on the nanocrystal surface.

### 3.1 INTRODUCTION

Titanium dioxide has been widely used in solar cells,<sup>1</sup> sensors,<sup>2</sup> batteries,<sup>3</sup> and photocatalysis.<sup>4</sup> Tuning of the mesoporous structure and composition of TiO<sub>2</sub> has been explored as a means to tailor optical, magnetic, photonic, electronic, and catalytic properties.<sup>5</sup> For instance, mesoporous TiO<sub>2</sub> has been shown to be a more effective catalyst because of its large surface area and pore structure that result in increased surface reactivity and improved mass transport. The facile preparation of ordered mesoporous electrodes with uniformly-sized pores that are oriented perpendicular to the substrate are desirable for facilitating charge-transfer and mass transport.<sup>6</sup> Unfortunately, most synthetic strategies that use structure directing templates for preparing mesoporous TiO<sub>2</sub> films produce pore architectures with large pore size distributions with pores that are either tortuous in nature or that run parallel to the substrate.<sup>7-12</sup> In sol-gel synthesis of TiO<sub>2</sub> films using structure-directing block copolymers, the ratio of surfactant, metal oxide precursor, and solvent may be adjusted to control the morphology, pore size, and pore orientation.<sup>13-16</sup> This route involves evaporation-induced self-assembly (EISA),<sup>17-20</sup> where the film geometry begins to form as the growth substrate is withdrawn from a solution containing both surfactant and metal oxide precursor. As the solvent evaporates, the local surfactant concentration increases to form micelles which guide the metal oxide precursor into hydrophilic regions to form phase segregated regions. Our group and others have demonstrated that anatase mesoporous TiO<sub>2</sub> thin films with perpendicular pores can be prepared on polymer modified glass,<sup>21</sup> silicon wafers,<sup>22</sup> and conducting ITO/glass substrates.<sup>23</sup> Similarly, Watkins and coworkers have prepared mesoporous silica films on silicon, by facilitating diffusion and condensation reactions with supercritical CO<sub>2</sub>.<sup>24</sup>

The incorporation of nanocrystals such as Au, Pt, and Ag into mesoporous TiO<sub>2</sub> is known to enhance optoelectronic and catalytic properties.<sup>25-30</sup> Metal/semiconductor films have typically been prepared by reduction of metal ion precursors inside a mesoporous thin film by heat, electrochemical deposition, or UV radiation.<sup>28, 29, 31-36</sup> However, with these methods it is difficult to control the nanocrystal morphology, size, and dispersion;

furthermore, the nanocrystals may grow until they block the pores.<sup>37</sup> To better control the nanocrystal composition, size, and dispersion within mesoporous powders, a novel approach has been developed in which pre-synthesized nanocrystals are infused into the mesoporous support.<sup>38-40</sup> Several methods have been used to drive nanocrystal infusion including sonication<sup>38</sup> and the addition of a nonsolvent, supercritical CO<sub>2</sub>, to an organic solvent such as toluene.<sup>39, 40</sup> The scCO<sub>2</sub> strengthens the nanocrystal–mesoporous silica interaction leading to higher loadings. The stabilizing ligand may be designed to be removed at low temperatures after infusion.<sup>40</sup> This technique provides excellent control over the morphology of the mesoporous support as well as the nanocrystal size, shape, and composition for the purpose of achieving high catalytic activities and stabilities.<sup>38, 40</sup>

An alternative approach to designing nanocomposite thin films is electrophoretic deposition of presynthesized nanocrystals on flat substrates such as carbon coated copper grids<sup>41, 42</sup> and ITO/glass.<sup>43, 44</sup> Kamat et al. have used this technique in organic solvents to deposit charged Au, Pt, and Ir nanocrystals onto films composed of disordered 10–40 nm TiO<sub>2</sub> nanocrystals.<sup>26, 27</sup> The film thickness depends upon both the concentration and deposition time. Metal nanocrystal layers formed by electrophoretic deposition are generally thicker than those formed by Langmuir Blodgett, self-assembled monolayer, or adsorption techniques. The aggregated nanocrystals form nanoporous films.<sup>45</sup> Thick films of CdSe nanocrystals deposited from an organic solvent, hexane, have been deposited electrophoretically onto conducting planar substrates composed of a 150 nm Au/10 nm Ti/Si wafer.<sup>46-48</sup> CdSe nanocrystals were also electrophoretically deposited selectively onto patterned Au films.<sup>46, 48</sup> Electrophoretic deposition produced more uniform films than dry casting or spin casting.<sup>46</sup>

Very few studies report electrophoretic deposition of nanocrystals into mesoporous thin films. Preferably, the pores of the film should be perpendicular to the substrate and aligned with the electric field.<sup>49, 50</sup> Limmer et al. have infused small nanoclusters inside porous membranes such as track-etched polycarbonate or anodic alumina with pore sizes of 100–200 nm and thicknesses to 10  $\mu\text{m}$ .<sup>51-54</sup> The nanoclusters completely filled the pores of the membranes and were heated to form nanowires. Zhang et al. used electrophoretic deposition to infuse 3 nm CdSe nanocrystals into thin polymer

films with 15 nm pores and a thickness of 30–40 nm.<sup>55</sup> In both of these studies, the pore to nanocrystal diameter ratio, while a tunable feature, was over 5.

The objective of this study was to achieve high loadings and deep penetration of 3.1 nm Au nanocrystals into 10 nm perpendicular pores in ~150 nm thick mesoporous TiO<sub>2</sub> thin films supported on conducting ITO/glass electrodes. The effect of electrophoresis on the kinetics and thermodynamics of deposition is analyzed by comparison with control experiments without an applied electric field for deposition times of 10 min and 20 hours. The electric field was varied as well as the nanocrystal concentration in the bulk phase. The electrical and structural properties of the prepared mesoporous TiO<sub>2</sub> thin films were characterized by scanning surface potential microscopy, atomic force microscopy, and scanning electron microscopy. UV–vis spectroscopy of the nanocomposite films was used to provide a relative measure of the nanocrystal loading. These loadings will be shown to be consistent with the absolute loadings determined by EDX and elemental analysis. Spectroscopic ellipsometry and X-ray photoelectron spectroscopy indicate that the Au nanocrystals penetrated deeply into the pores of the TiO<sub>2</sub> film with a maximum loading of 21% by weight and 12% by volume. The influence of the various properties including the nanocrystal size, pore diameter, electrophoretic mobility, electric field strength, and local deposition rate constant on the mean penetration depth of a single nanocrystal was analyzed based on an electrophoretic deposition model, which is based on the Fokker-Planck equation.<sup>56, 57</sup> From the experimental mean deposition distance in the pores, a rate constant was estimated from the model. The penetration depth of the nanocrystals depends upon the strength of the nanocrystal-wall interactions, which are influenced by the coverage of the metal surface by the dodecanethiol ligands. The presynthesis of both the nanocrystals and the mesoporous thin films is shown to be a useful approach to control the nanocrystal shape, size, composition, and dispersion within the pores, as well as the mesoporous structure of the thin film.

## 3.2 EXPERIMENTAL SECTION

### 3.2.1 Materials

All chemicals were used as received. Titanium (IV) isopropoxide ( $\text{Ti}(\text{O}\cdot i\text{-C}_3\text{H}_7)_4$ ) (97 %), hydrogen tetrachloroaurate(III) trihydrate ( $\text{HAuCl}_4\cdot 3\text{H}_2\text{O}$ ) (99.9%), tetraoctylammonium bromide ( $((\text{C}_8\text{H}_{17})_4\text{-NBr})$  (98%), sodium borohydride ( $\text{NaBH}_4$ ) (99%), and 1-dodecanethiol ( $\text{C}_{12}\text{H}_{25}\text{SH}$ ) (98%) were purchased from Sigma-Aldrich Cooperation, and toluene (99.9%), chloroform (99.9%), hydrochloric acid ( $\text{HCl}$ ) (35.5 %), ethanol ( $\text{C}_2\text{H}_5\text{OH}$ ) (Absolute 200 proof), and 2-propanol ( $((\text{CH}_3)_2\text{CHOH})$  (99.9 %) from Fisher Scientific. Non-ionic triblock copolymer surfactant Pluronic P123 (poly-(ethylene oxide) poly-(propylene oxide) poly-(ethylene oxide)  $\text{EO}_{20}\text{-PO}_{70}\text{-EO}_{20}$ ) was supplied by BASF. Water ( $\text{H}_2\text{O}$ ) was double-distilled and deionized. ITO/glass substrates were purchased from Delta Technologies, Limited.

### 3.2.2 Preparation of Substrates

The substrates for the mesoporous thin films were prepared as described elsewhere.<sup>23</sup> ITO/glass slides were cut into 1 x 1 cm<sup>2</sup> sections, rinsed using 2-propanol, and blown dry in air flow. A  $\text{TiO}_2$ -buffer layer was coated on the ITO/glass substrate by chemical solution deposition. The purpose of the buffer layer is to increase the surface energy of the substrate to facilitate self-assembly of the polymer micelles to template the mesoporous structure. Ti solution was prepared by mixing 0.03 g of  $\text{Ti}(\text{O}\cdot i\text{-C}_3\text{H}_7)_4$  and 10 cm<sup>3</sup> of 2-propanol. ITO/glass substrates were dip-coated with a speed of ~ 6.0 cm/min, followed by heat-treatment at 200°C for 5 min in air for drying and polymerization. The film thickness of the  $\text{TiO}_2$  buffer layer was estimated to be approximately 2 nm by spectroscopic ellipsometry.<sup>23</sup>

### 3.2.3 Preparation of Mesoporous Titania Films

Mesoporous titania films were prepared by self-assembly of block copolymer surfactants in sol-gel solution as described elsewhere.<sup>22, 23</sup> 1.05 g of  $\text{Ti}(\text{O}\cdot i\text{-C}_3\text{H}_7)_4$  was hydrolyzed using 0.74 g of concentrated aqueous  $\text{HCl}$  under stirring for 10 min at room temperature. The hydrolyzed sol was mixed with 0.2 g of P123 surfactant dissolved in

3.0 g of ethanol while stirring for 15 min at room temperature. The resulting solution was spin-coated on the substrates at a rate of ~7500 rpm for 60 seconds, followed by aging at  $-10^{\circ}\text{C}$  for 2 days under a controlled humidity of ~45–55%. The samples were subsequently calcined using a tube furnace at  $400^{\circ}\text{C}$  for 4 hours in air with a heating rate of  $1.0^{\circ}\text{C}/\text{min}$  to remove the block copolymer template and fix the mesoporous structure of the film.

### 3.2.4 Au Nanocrystal Synthesis

Au nanocrystals were synthesized by a two-phase arrested precipitation technique.<sup>58, 59</sup> 15 mL of aqueous (0.064 M) hydrogen tetrachloroaurate(III) trihydrate ( $\text{HAuCl}_4 \cdot 3\text{H}_2\text{O}$ ) was combined with 25 mL of toluene solution containing 2.7 g of phase transfer catalyst, tetraoctylammonium bromide. After stirring for 1 h, the organic phase, with the transferred Au, was collected. The Au salt was then reduced using 15 mL of an aqueous sodium borohydride ( $\text{NaBH}_4$ ) solution (0.44 M), resulting in Au nanocrystals dispersed in toluene, protected by the phase transfer catalyst. To this solution, 0.240 mL of dodecanethiol was added 1 hr later and stirred for 1 more hr. The Au nanocrystals were washed and size selected using ethanol as an antisolvent. Finally, the Au nanocrystals were dispersed in chloroform. The Au nanocrystals were  $3.1 \pm 0.7$  nm as measured by transmission electron microscopy with 1.9 nm length dodecanethiol<sup>60</sup> capping ligands.

### 3.2.5 Au/TiO<sub>2</sub> Composite Formation

In the electrophoretic deposition process, the mesoporous TiO<sub>2</sub> on ITO/glass was the negative electrode. Electrical contact was made on the naked edge of the ITO substrate to ensure good electrical contact. The positive counter electrode was bare ITO/glass with the same dimensions. The electrodes were spaced 3 mm apart and completely immersed in a 2.5 mL Au nanocrystal dispersion (~0.1–0.2 mg/mL) in chloroform. A potential of 25 or 50 V was applied for 10 min to infuse the Au nanocrystals inside the mesoporous TiO<sub>2</sub> film. A control experiment was done by dipping the mesoporous TiO<sub>2</sub> film in the Au nanocrystal dispersion (~0.1 mg/mL) for 10 min and 20 hours without an applied electric field. The Au nanocrystal dispersion

showed no visual change in concentration (color) after nanocomposite formation, consistent with the very large number of nanocrystals in the bulk solution versus the small amount adsorbed.

### 3.2.6 Characterization

The microstructure of the mesoporous film was observed using a Zeiss Supra 40VP field emission scanning electron microscope. The SEM observation was performed at an accelerating voltage of 5–10 kV. UV–vis spectra were measured using a Varian Cary 5000 spectrophotometer. Scanning surface potential microscopy measurements of the mesoporous  $\text{TiO}_2$  were performed on a Veeco Bioscope Atomic Force Microscope (AFM) with a Nanoscope IV controller. Scan sizes were  $1 \times 1 \mu\text{m}$ , and the scan rate was 1 Hz. The interleave scan used for surface potential measurements was fixed at 10 nm.<sup>61</sup> Potentials were applied to the mesoporous film by connecting the ITO support to the sample stage with conductive Cu tape. The SSPM probes used for data collection were custom fabricated from NSC15/Ti-Pt (Mikromasch) Pt coated AFM probes. Previous experiments have shown these probes have insufficient resolution for nanoscale SSPM studies,<sup>62, 63</sup> so they were modified in a dual-beam focused ion beam (FEI DB235) with a 30 keV beam and beam current of 20 nA. Cone angles of the probes were reduced from 30° to 10°, and tip radii were unchanged.

X-ray photoelectron spectroscopy was done with a PHI 5700 XPS system using a monochromatic Al X-ray source. The system was calibrated using Au4f, Ag3d, and Cu2p peaks. Ar ions at 3 kV and a 45° angle were used to sputter the sample for a known length of time. The sample was measured with XPS for Au and Ti after each sputtering time. The bottom of the film was defined as the point where a large increase in the amount of In was detected. Energy dispersive X-ray analysis was performed using a LEO 1530 SEM equipped with an IXRF EDX system, the latter operated with a 20 kV electron beam and 60  $\mu\text{m}$  aperture (average counts  $\sim 2000 \text{ s}^{-1}$ ). Elemental analysis was done with a Varian GTA120 AA240-Z graphite tube atomizer. Nanocomposites were dissolved in aqua regia overnight. The solution containing Au ions was then analyzed to determine the Au content.

A J.A. Woolam M-2000 variable angle spectroscopic ellipsometer was used to determine the ellipsometry parameters  $\Psi$  and  $\Delta$  from 200 to 800 nm at three different angles, 60°, 65°, and 70°. The same instrument was also used to record p-polarized transmission measurements from 300 to 800 nm. In order to extract the films thickness as well as the real (n) and imaginary (k) portion of the complex refractive index, the data was fit using a three layer model consisting of a glass substrate, indium tin oxide,<sup>64</sup> and the film layer. As described previously<sup>23</sup> mesoporous TiO<sub>2</sub> was modeled assuming isotropic optical constants with a Tauc-Lorentz (T-L) oscillator for the band gap and two additional Gaussian oscillators. Upon Au infusion this isotropic approximation did not adequately describe the ellipsometry and transmission data. As a result an anisotropic uniaxial model was used to model the TiO<sub>2</sub> films following Au infusion. The ordinary (x-y plane) portion of the uniaxial model used a T-L oscillator<sup>65</sup> for the band gap, a large Gaussian above the band gap whose tail also accounted for small Urbach absorption below the band gap, a Gaussian in the visible describing the Au plasmon band, and finally a Drude oscillator<sup>66</sup> accounting for broad free carrier type adsorption. The extreme (z plane) refractive index used the same T-L oscillator with a Gaussian above the band gap but absorption in the visible was modeled with only a Drude oscillator. A more complex description of the extreme absorption was not necessary, and the simple two variable Drude model is desirable because of the large number of fit parameters already present in the model.

### 3.3 RESULTS

Figure 3.1 shows an SEM image of the mesoporous TiO<sub>2</sub> films with a hexagonal close-packed geometry. The top down view in Figure 3.1a shows ~10 nm pores spaced apart by ~10 nm nanopillars on a TiO<sub>2</sub> buffered ITO/glass substrate. The inverse mesospace (pores) and nanopillars run perpendicular to the ITO conducting substrate as seen in the cross-section view of Figure 3.1b and the schematic of Figure 3.1c. Evenly spaced pillars are present with a continuous void space. The film thickness ranges from

Figure 3.1: SEM image of  $\sim 110$  nm mesoporous  $\text{TiO}_2$  thin film on ITO/glass with  $10 \pm 2$  nm pores and  $10 \pm 2$  nm pillars. (a) top down view, (b) cross-section view, and (c) schematic of perpendicular nanpillars on ITO/glass.

~100–150 nm. The layer underneath the TiO<sub>2</sub> film is the conducting ITO which is approximately 60–100 nm thick as indicated by the manufacturers.

To gain insight into the electrical properties of the TiO<sub>2</sub> film without any Au, scanning surface potential microscopy was performed to determine the potential drop across the TiO<sub>2</sub> film. The AFM topography scan in Figure 3.2a resembles the structure seen in the SEM image (Figure 3.1a). The underlying ITO substrate was connected to an external voltage source and potentials of 0.0, 5.0, and 10.0 V were applied. Measured surface potentials were within 1% of the applied potential, thus the TiO<sub>2</sub> did not appreciably reduce the applied bias as shown in crosssectional surface potential line scans (Figure 3.2b). This suggests that there is no large ohmic drop that would signify a highly resistive TiO<sub>2</sub> film. These small potential drops indicate that there is very little difference between the applied potential applied to the ITO electrode and the measured potential at the top of the TiO<sub>2</sub> film.

While the measured surface potentials were similar to the applied potential on large scales, nanoscale potential differences due to the porous symmetry of the film could not be resolved with conventional AFM probes. These potential differences, while very small in magnitude in comparison to the large potentials applied to the sample, are important to understand as they may influence Au nanocrystal transport within the mesoporous TiO<sub>2</sub> film. The determination of potential differences on such small size scales is not possible with conventional probe geometries,<sup>67, 68</sup> because they have a large tip diameter (~30 nm) and a cone angle of approximately 30°. This large tip diameter and cone angle leads to a large averaging effect in surface potential imaging and greatly reduces the resolution of the measurement.<sup>62, 63</sup> Successful imaging of the minute differences in surface potential along the surface of the TiO<sub>2</sub> required an AFM probe with a much smaller cone angle. To obtain the desired geometry, the probes were milled in a focused ion beam (FIB) to a resulting cone angle of 10° with a tip radius ≤ 20 nm. While the topographical resolution was very similar to that obtained with conventional Pt coated probes (Figure 3.3a), surface potential sensitivity was improved significantly. The mesoporous symmetry of the TiO<sub>2</sub> was clearly visible in the surface potential images, where potential differences between the mesopores and pore walls were typically 50 mV

Figure 3.2: (a) 1 x 1 micron AFM topography image of the  $\text{TiO}_2$  surface structure. (b) Crossectional line plots of surface potential measured across  $\text{TiO}_2$  surface. Only a 1% error between the potential measured at the  $\text{TiO}_2$  surface and that applied to the underlying ITO substrate indicates that the  $\text{TiO}_2$  film had very little effect on the electrophoretic fields used for the Au nanocrystal insertion.

Figure 3.3: (a) 500 x 500 nm AFM topography image of Au/TiO<sub>2</sub> nanocomposite. (b) 500 x 500 nm surface potential image of (a) shows clear resolution of the porous structure. (c) Data from the line indicated in (a) and (b) shows typical potential differences (blue line) between the pore and the pillars (black line) of the Au/TiO<sub>2</sub> nanocomposite.

(Figure 3.3b). SSPM imaging of the Au/TiO<sub>2</sub> nanocomposite with no applied potential bias (0 V) showed surface potentials that were 50–90 mV higher in the mesopores relative to the pore walls (Fig. 3.3c). Presumably, this potential difference was found to be influenced by the addition of the Au nanocrystals in the pores since TiO<sub>2</sub> films without Au exhibit a potential difference between pores and pillars of the film below the noise floor of 12 mV (Appendix A, Figure A.1).

UV–vis spectroscopy of the Au/TiO<sub>2</sub> films is shown in Figure 3.4. The spectra have been normalized to an absorbance of 0 at 720 nm to aid visual comparison. A peak at ~515 nm is clearly present associated with the surface plasmon resonance (SPR) of Au. As shown in Figure 3.4a and Table 3.1, control experiments without an applied field at 10 min. and 20 hours gave the lowest absorbances of 0.987 and 1.05, respectively. The similar absorbance values indicated that the nanocrystal incorporation was not kinetically limited over 10 min, but thermodynamically limited. Figure 3.4a shows a control experiment in which the absorbance spectrum for Au/TiO<sub>2</sub> composite assembled by immersion for 20 hours without an applied voltage exhibits a peak of diminished absorbance at 502 nm corresponding to roughly a 33% decrease in absorbance relative to Au/TiO<sub>2</sub> composites assembled with an applied electric field (Figure 3.4b). Very similar results were obtained in 10 min. without an applied voltage. Brownian motion led to significant deposition, but less than in the electrophoretic deposition experiments with an applied field. Figure 3.4b shows the spectra for Au nanocrystals deposited electrophoretically at two different electric field strengths, 83 and 167 V/cm, corresponding to 25 and 50 V, respectively. There was a slight increase in the maximum absorbance on doubling the electric field, as shown in Table 3.1. Increasing the nanocrystal dispersion concentration by approximately a factor of two nearly doubled the maximum absorbance in the nanocomposite as shown in Figure 3.4c and Table 3.1 at a given field of 83 V/cm. Also the amount of nanocrystals loaded in each case was less than 2% of the total number of nanocrystals in bulk, so that the concentration of nanocrystals in the solution can be assumed to be constant.

Figure 3.4: UV-vis spectroscopy of Au/TiO<sub>2</sub> nanocomposites. Experimental conditions: (a) ~0.1 mg/mL, 20 hrs, 0 V, (b) ~0.1 mg/mL, 10 min, 25 or 50 V, and (c) ~0.2 mg/mL, 10 min, 25 V.

Table 3.1: Maximum absorbance for surface plasmon resonance of Au for initial Au concentration of 0.1 mg/mL and 10 min. deposition time.

	Max Abs
Control (0 V)	0.987
Control (0 V) <sup>a</sup>	1.05
25 V	1.4 ± 0.2
50 V	1.50 ± 0.04
25 V <sup>b</sup>	2.49

<sup>a</sup>Deposition time was 20 hours. <sup>b</sup>Initial Au nanocrystal concentration = 0.2 mg/mL.

The complicated oscillating absorbance spectrum, which is most prevalent in Figure 3.4a with the lowest Au deposition, is attributed to interference effects occurring from the multiple interfaces comprising the ordered mesoporous film. The interfaces between the TiO<sub>2</sub>, ITO, and glass produce interference fringes leading to the oscillations in the absorbance even with no Au present (Appendix A, Figure A.2). Small shifts of the SPR can also be seen in the spectra and can be attributed either to the slight changes in the relative dielectric constant in the immediate vicinity of the nanocrystal or to the interference effects from the films.

SEM EDX and elemental analysis of the Au/TiO<sub>2</sub> nanocomposite films were utilized to further quantify the nanocrystal loadings for a constant nanocrystal concentration of 0.1 mg/mL. As shown in Table 3.2, the values from SEM EDX are slightly higher than those obtained from elemental analysis, but are within experimental error for two of the three conditions. The control experiment without an applied potential gave the lowest amount of Au incorporation with a loading of ~4 wt% by SEM EDX for 10 min and ~4.6 wt% by SEM EDX and ~4.7 wt% by elemental analysis for 20 hours, where wt% reflects the amount of Au relative to the total weight of Au and TiO<sub>2</sub>. In comparison pore filling for the control experiments led to Au loadings of 1.9 and 2.3 vol%, respectively, where vol% is volume of Au over the film pore volume. The SEM EDX data for the control experiment further corroborate that the loadings are thermodynamically limited and not kinetically limited as nanocrystal adsorption reaches equilibrium in 10 min. The loadings were comparable for the nanocomposites made by electrophoretic deposition at the two electric field strengths of 83 and 167 V/cm, on the order of 8 wt% (~4.0 vol%). The small effect of doubling the electric field confirmed the results from UV-vis spectroscopy (Figure 3.4 and Table 3.1). For the more concentrated Au dispersion (0.2 mg/mL), the loading reached ~21 wt% Au according to SEM EDX at 83 V/cm. With this highest loading, the amount of pore volume occupied is 12 vol%. The ratio of loadings at 0.2 versus 0.1 mg/mL dispersion was comparable with a ratio of ~1.7 from SEM EDX and ~1.8 from the absorbance maxima from UV-vis spectroscopy.

Table 3.2: Au loading as determined by SEM EDX and elemental analysis for initial Au concentration of 0.1 mg/mL and 10 min deposition time.

	SEM EDX (wt%)	Elemental Analysis (wt%)	Volume %
Control (0 V)	$4 \pm 1$	-	1.9
Control (0 V) <sup>a</sup>	$4.6 \pm 0.5$	4.7	2.3
25 V	$12 \pm 2$	7.9	4.0
50 V	$9 \pm 3$	8.2	4.1
25 V <sup>b</sup>	$21 \pm 5$	-	12

<sup>a</sup>Deposition time was 20 hours. <sup>b</sup>Initial Au nanocrystal concentration = 0.2 mg/mL.

A top down view SEM image of the Au/TiO<sub>2</sub> nanocomposite film is given in Figure 3.5b. The empty porous TiO<sub>2</sub> film is provided in Figure 3.5a for easier comparison with the synthesized Au/TiO<sub>2</sub> nanocomposite. The Au nanocrystals are evenly dispersed across the TiO<sub>2</sub> film. The depth of field is limited by the short working distance of the microscope making it difficult to image deep within the pores. Thus, this orientation does not provide depth resolution for these nanocrystals with respect to the mesopores. In Figure 3.5a the mesopores of the film are seen as dark spots. In Figure 3.5b, the pores of the film are not as dark, possibly indicating the presence of Au nanocrystals within the pores. The nanocrystals in the image retain their size and shape after electrophoretic deposition without aggregation. The SEM images were very similar for nanocomposites produced by electrophoretic deposition and adsorption without an electric field. The nanocrystal diameter in Figure 3.5b is  $3.7 \pm 0.8$  nm. This size is only slightly larger than the as-synthesized nanocrystal size of  $3.1 \pm 0.7$  nm and is attributed to the difficulty in sizing the nanocrystals from the image due to the blurred edges.

Figure 3.5: SEM top down view of (a) mesoporous  $\text{TiO}_2$  and (b)  $\text{Au/TiO}_2$  nanocomposite.

The films were further characterized by variable angle spectroscopic ellipsometry. Despite the anisotropic geometry of the columnar mesoporous  $\text{TiO}_2$ , good model fits of ellipsometric and transmission data have been obtained by assuming isotropic films, that is, the same optical constants regardless of orientation.<sup>23</sup> However, for Au infused films, the best fit isotropic model is unsatisfactory and overestimates  $\Psi$  from ~450 to 650 nm and  $\Delta$  from ~570 to 800 nm (Figure 3.6). A uniaxial anisotropic model, in which the film's z axis has different optical constants than the x and y axis, remedies this problem resulting in good fits across the spectral range. The extracted optical constants (Figure 3.7) provide insight into how Au is loaded into the film. Mesoporous  $\text{TiO}_2$  behaves like a classic semiconductor with no absorption and normal dispersion before the band gap and a sharp increase in absorbance in the UV corresponding to a band gap transition. Following infusion of ~21 wt% Au the ordinary, x-y plane, optical constants ( $n_o$  and  $k_o$ ) of the film are similar to those found before infusion with the addition of a plasmon absorbance at ~550 nm and a small broad absorbance extending out into the near IR (Figure 3.7b). This extra absorbance shifts  $n_o$  upward due to the Kramers-Kronig relationship (Figure 3.7a). A similar attenuation of absorbance in the visible to near IR was observed by Granqvist and Hunderi<sup>69</sup> for individually isolated 3 to 4 nm Au nanocrystals.

The extreme (z plane) imaginary refractive index,  $k_e$ , is significantly enhanced compared to the weak absorbance, small  $k_o$ , of the x-y plane (Figure 3.7b). This large absorbance in the visible to near IR arises from free electron absorbance due to the formation of a conduction band by overlapping orbitals, indicating that the Au nanocrystals are in close contact.<sup>69</sup> From these observations two important conclusions are reached. First, the lack of absorbance in the x-y plane means that any residual Au nanocrystals on the  $\text{TiO}_2$  surface are so dispersed that they are not in contact with each other. This corroborates SEM data which indicates that very few nanocrystals are located on the surface, and implies that most of the Au detected by elemental analysis and EDX is packed into the  $\text{TiO}_2$  mesopores. Inside the mesopores the small pore diameter limits lateral contact between the nanocrystals in the x-y plane. Second, the large absorbance in the z direction means that light oriented in this direction 'sees' more of the free electron

Figure 3.6:  $\Psi$  (a),  $\Delta$  (b), and %T (c) experimental (line) and model fits (symbols) for best fit isotropic (square) and uniaxial (triangle) models of mesoporous  $\text{TiO}_2$  infused with 21 wt. % Au. The misfit of the isotropic model in the visible region justifies the inclusion of anisotropy using the more complex uniaxial model.

Figure 3.7: Real (a) and imaginary (b) components of the complex refractive index for mesoporous  $\text{TiO}_2$  (green dots) as well as the normal (solid) and extreme (red dash) refractive index of mesoporous  $\text{TiO}_2$  infused with 21 wt. % Au. The large  $k_e$  in the visible spectrum indicates alignment of the Au particles along the film's  $z$  axis.

absorption associated with nanocrystals in contact with one another. Since the z direction is oriented with the film's columnar mesopores, the obvious conclusion is that the Au nanocrystals are loaded vertically into the pores.

XPS was performed on the 21 wt% Au/TiO<sub>2</sub> nanocomposite film. Figure 3.8 shows the Au concentration as a function of sputtering time and film depth. The sample was sputtered for a certain length of time and the Au concentration was measured relative to the Ti concentration. A simple linear correlation between sputtering time and the film thickness was used to generate the depth profile. The time where a sharp increase in the indium concentration occurred was used as the time at which the film bottom was reached. Many of the Au nanocrystals reside near the top half of the mesoporous TiO<sub>2</sub> film. The Au concentration steadily decreases with film depth. Although there are a significant number of Au nanocrystals near the bottom of the film, this value could be inflated by small amounts of Au being forced downward into the film by the sputtering process. The average Au concentration throughout the film thickness was ~20 wt% in good agreement with the SEM EDX value of 21 wt%.

Figure 3.8: Au4f XPS depth profiling experiment. Plot of Au wt % versus sputtering time and depth for 21 wt% Au in mesoporous  $\text{TiO}_2$  thin film.

### 3.4 DISCUSSION

A significant amount of nanocrystals were adsorbed onto the TiO<sub>2</sub> surface even in the absence of an applied potential. This loading was caused by the interaction between the nanocrystals and TiO<sub>2</sub> surface along with rapid diffusion through the pores due to the high ratio of the film's internal surface area to the top surface area (~26:1). This adsorption is over an order of magnitude larger than for similar dodecanethiol coated nanocrystals into mesoporous silica particles.<sup>39</sup> The greater adsorption is facilitated by the stronger interaction of the nanocrystals with TiO<sub>2</sub>. Higher activities have also been reported for Au/TiO<sub>2</sub> relative to Au/SiO<sub>2</sub> for CO oxidation<sup>70, 71</sup> implying that the interaction of Au with TiO<sub>2</sub> is stronger than Au with SiO<sub>2</sub>. The increase in nanocrystal loading with the application of an electric field may be caused by: (1) an increase in the local nanocrystal concentration at the pore entrance produced by electrophoresis, (2) a change in the nanocrystal-TiO<sub>2</sub> interaction based on the surface charge on the TiO<sub>2</sub>, or (3) deeper penetration into the pores caused by an enhancement in the electrophoretic velocity in the pores. The SSPM measurements suggest that the pores of the TiO<sub>2</sub> film extend throughout the length of the film thickness, as the surface potential measured across the pores is slightly larger as compared to the pore walls. The electric field in the pores described by this gradient can produce electrophoresis within the pores.

Theoretical calculations of a close-packed surface coverage of a monolayer of nanocrystals on the top planar TiO<sub>2</sub> film surface will now be used to show that the majority of the nanocrystals are contained within the pores. From an analysis of Figure 3.1, the area fraction of voids on the top surface of the film is ~30%. Consequently, the top planar surface area for the pillars is 1.7 m<sup>2</sup>/g TiO<sub>2</sub> for a film thickness of 150 nm. For 3.1 nm diameter Au nanocrystals, the area/g of a nanocrystal is 25 m<sup>2</sup>/g Au. A close-packed monolayer with a packing density of 0.907 (2D hexagonal) of Au nanocrystals on the top planar surface of TiO<sub>2</sub> would correspond to a loading of 5.9 wt%, or equivalently, ~9 nanocrystals on top of each pillar. The highest experimental loading (~21 wt%) was more than three times greater than this close-packed value. Moreover, Figure 3.5b

indicates the amount of Au on the top planar film surface of ~0.3 wt% Au is far below the close-packed value, and the VASE results also indicate that the nanocrystals are dispersed in the pores of the film. Hence, the vast majority of nanocrystals are within the pores and not on the top surface.

The experimental loading may be compared with the theoretical loading for a monolayer of Au nanocrystals on each pillar. For films with ~8 wt% (4.0 vol%, relative to the film pore volume) and ~21 wt% (12 vol%) Au loading, there would be ~30 and ~90 nanocrystals, respectively, around each pillar, if all of the nanocrystals were associated directly with a pillar. These values were estimated by dividing the total number of nanocrystals by the number of pillars. These 90 nanocrystals would cover ~15% of the pillar surface area, excluding the surface area on top of the pillar. The nanocrystals inside the film are closer together than this value of 15% in z-direction, but not along the nanopillar circumference. Assuming a maximum packing fraction of 74 vol% for spheres inside of the void volume of the film (porosity = 30% from Figure 3.1), the maximum loading would be 62 wt % Au, corresponding to ~560 nanocrystals per pillar. With the ~10 nm gap between pillars, not all of the nanocrystals would be required to be directly on a pillar. For example another 4 nm would be available between two pillars after attaching two 3.1 nm nanocrystals directly on the pillars. Of the estimated 560 nanocrystals around each pillar, ~470 would be directly attached to the pillar surface (62 vol% of the max. 74 vol% packing in the total void volume) and ~90 would be found in the annular region (12 vol%). Hence, even with the experimental number of nanocrystals adsorbed directly onto the pillars, there exists sufficient space for more nanocrystals to access the pores of the film. The tortuosity of the pores may be expected to inhibit nanocrystals from reaching the film bottom, although diffusion in the circumferential direction for the interconnected annuli is favorable. Thus, the apparent thermodynamic limit after 10 minutes is likely not the true thermodynamic limit for perfect nanopillar geometry. XPS shows that the distribution of nanocrystals favors the upper regions of the film.

The motivation for using a low dielectric constant ( $\epsilon$ ) nonpolar organic solvent in this study was several-fold. In a polar solvent such as water or ethanol, the charge on the

surface of a Au nanocrystal may be achieved more readily, and the higher  $\epsilon$  favors a higher electrophoretic mobility. However, the nanocrystal size of Au may be controlled more precisely for synthesis in nonpolar solvents.<sup>58</sup> Furthermore, both positive and negatively charged nanocrystals may be present simultaneously in low  $\epsilon$  organic solvents. Also, electrochemical reactions at the electrode surface such as hydrogen and oxygen evolution in the case of water are avoided with an inert organic solvent. With organic solvents, higher potentials ( $>5$  V) can be used without the problems of electrolysis and joule heating.<sup>72, 73</sup> Using conservative estimates, the temperature increase during an electrophoretic deposition experiment would be only  $\sim 0.2$  K at 50 V applied.<sup>74</sup> However, the potentials in this study were kept low enough to avoid electrohydrodynamic instabilities and other nonlinearities. Potentials were kept below the critical voltage as given by the laminar-to-turbulent transition voltage equation<sup>75</sup>

$$V_{inst} = \frac{30\eta}{\sqrt{\rho\epsilon_r\epsilon_o}} \quad (3.1)$$

where  $\eta$  is the solvent viscosity,  $\rho$  is the solvent density,  $\epsilon_r$  is the relative dielectric constant, and  $\epsilon_o$  is the permittivity of free space. For chloroform,  $V_{inst} = 64.5$  V ( $\eta = 0.539$  cP,  $\rho = 1.48$  g/mL, and  $\epsilon_r = 4.8$ ). Hence, the potentials applied in this study, 50 V maximum, were well below the threshold value.

The Au nanocrystals dispersed in chloroform possess an excess positive charge as the darkly colored nanocrystals were observed to accumulate near the negative electrode, while the region near the positive electrode became transparent, when an electrophoretic potential of 25 V was applied for an electrode spacing of 3 mm. While the surface charge on the Au nanocrystals was not determined quantitatively, Zheng et al. have previously reported a distribution of electrophoretic mobilities for 3.5 nm Au nanocrystals capped with dodecanethiol ligands dispersed in chloroform.<sup>76</sup> Roughly 85% of the nanocrystals had mobilities ranging between 0.1 to 0.5 ( $\mu\text{m/s}/(\text{V/cm})$ ) while a smaller percentage exhibited values from -0.2 to 0.1 ( $\mu\text{m/s}/(\text{V/cm})$ ). Hence, a large majority of the nanocrystals exhibit a positive charge. Since the Au nanocrystals in the present study were synthesized by similar means, a comparable distribution of mobilities and charges may be expected. Although the origin of the surface charge was not given by Zheng et

al., it is possible that loss of dodecanethiol capping ligands can result in an excess positive charge on the nanocrystal.<sup>77</sup> The electrophoretic mobility ( $\mu$ ) is related to the surface charge (Q) by

$$Q = 6\pi\mu\eta a \quad (3.2)$$

where  $a$  is the nanocrystal radius. The reported average mobility of  $0.30 \text{ } (\mu\text{m/s})/(\text{V/cm})$ <sup>76</sup> translates to a surface charge of  $5.4 \times 10^{-20} \text{ C}$  per nanocrystal or a charge of  $+0.34$  per nanocrystal.

In general, the mechanism of electrophoretic deposition involves electrophoresis of particles, along with deposition on the surface.<sup>72, 78</sup> The velocity of the nanocrystals ( $v$ ) can be estimated from the measured  $\mu$  of Zheng et al<sup>76</sup> from the relationship

$$v = \mu E. \quad (3.3)$$

The calculated velocities were  $25 \text{ } \mu\text{m/s}$  and  $50 \text{ } \mu\text{m/s}$  for electric fields of  $83 \text{ V/cm}$  and  $170 \text{ V/cm}$ , respectively, assuming an electrophoretic mobility of  $0.30 \text{ } (\mu\text{m/s})/(\text{V/cm})$ .<sup>76</sup> With the electrode spacing maintained at  $3 \text{ mm}$ , the charged nanocrystals at the positive electrode would require  $\sim 120 \text{ s}$  and  $\sim 60 \text{ s}$ , respectively, to reach the  $\text{TiO}_2$  surface at the negative electrode. With the nanocrystals congregated at the  $\text{TiO}_2$  film surface, the effective concentration at the film surface is greatly increased compared to the initial concentration as with the control experiment with no electric field. A kinematic shock layer<sup>79</sup> may form with a sharp increase in the local concentration next to the film compared to the bulk. The higher local nanocrystal concentration at the pore entrance will raise the chemical potential of the nanocrystals and thus drive adsorption.<sup>72, 78</sup> Additionally, fluid flow around the pore opening can accelerate particle insertion into the pores<sup>55, 80, 81</sup> although this behavior is not well understood in organic media with large double layers. The potential drop which occurs across the pore length measured by SSPM is capable of producing electrophoresis and electro-osmosis.<sup>56, 57, 82</sup>

Haber et al. have developed a model to describe the average depth of penetration of a single particle inside a long cylindrical pore using the Fokker-Planck equation for the probability distribution.<sup>56, 57</sup> The model takes into account the stochastic and electric field induced motion of the particle and the fluid. The electric field is aligned in the axial direction. The effects of electrophoresis, diffusion, and deposition onto the substrate may

be characterized by two key numbers, the Peclet number (Pe–ratio of convection to diffusion) and the Damkohler number (Da–ratio of deposition to diffusion),<sup>56, 57</sup> defined as

$$Pe = v_t b / D \quad (3.4)$$

$$Da = \kappa b / D \quad (3.5)$$

where  $v_t$  is the sum of the electrophoretic and electro-osmotic velocities,  $b$  is the mean pore radius,  $\kappa$  is the local deposition rate, and  $D$  is the diffusion coefficient. From the SSPM data, the potential drop across the film, and by assumption the pore channel, was measured to be ~1%. For a 25 V bias, the potential drop would be ~0.25 V across a pore length of 150 nm, corresponding to an electric field of ~17 kV/cm in the pore. From eq. 3.3, the nanocrystal electrophoretic velocity is 5.0 mm/s using an electrophoretic mobility of 0.30 ( $\mu\text{m/s})/(\text{V/cm})$ <sup>76</sup>, and  $Pe = 0.096$ . With the pores closed at one end at the ITO substrate, no net volume flow exits the pore channel. Microscopic flows are possible with nonlinear velocity profiles to account for conservation of volume, but with the small pore size of only 10 nm and the low concentration of ions in the system, the electroosmotic flow is assumed to be negligible. Thus, the total velocity is given by the electrophoretic velocity,  $v$ , through the pore, and  $Pe$  remains 0.096.

The local deposition rate is unknown and depends upon many factors including the particle shape and size, electrostatic, van der Waals and hydrodynamic forces, as well as specific chemical interactions between Au and the substrate.<sup>57</sup> However,  $\kappa$  may be approximated from an electrophoretic model<sup>57</sup> given the experimental average depth of nanocrystal penetration inside the pore channel from XPS data. Assuming an average depth of the nanocrystal in the pore,  $z$ , as ~50 nm, the dimensionless mean penetration depth ( $\chi$ )

$$\chi = z / (b \times Pe) \quad (3.6)$$

is 105. Since the electro-osmotic velocity is assumed to be very small, we chose the lowest ratio of the electro-osmotic to electrophoretic velocity,  $\zeta$ , considered in the model,  $\zeta = 0.1$ .<sup>57</sup>

Haber et al developed a correlation to fit the results from the Fokker-Planck equation<sup>57</sup>

$$\chi = -\frac{1}{15} + \frac{1}{\zeta} \left( \frac{1}{3} + \frac{1}{Da} \right) \quad (3.7).$$

From equation 3.7, Da is approximately 0.099 given our values of  $\chi$  and  $\zeta$ . Thus the local deposition rate,  $\kappa$ , is 0.52 cm/s. This unusually small Da results from the extremely small pore radius,  $b$ . The relatively weak Au-wall specific interactions, given the high surface coverage and strong binding of the dodecanethiol ligands, and small nanocrystal radius may lower  $\kappa$ . For example, similar Ag nanocrystals were shown to have a dodecanethiol surface coverage of  $\sim 75\%$ .<sup>83</sup> However, the Au-TiO<sub>2</sub> interactions were strong enough to produce reasonably high loadings even with no applied electric field ( $E = 0$ ). The low Da, favors relatively deep penetration of a nanocrystal inside the pore (high  $\chi$ ), despite the low Pe. The low Pe results from the small pore radius,  $b$ , and low dielectric constant,  $\epsilon$ , which leads to a small mobility and small velocity,  $v$ . Upon deposition of the nanocrystal onto the negatively charged TiO<sub>2</sub> pore wall, charge neutralization most likely occurs.<sup>46, 47</sup> Thus, the neutral deposited nanocrystal will not repel incoming charged nanocrystals electrostatically.

Figure 3.9 shows the relationship between the average depth of the nanocrystal in the pore  $z$  vs. Pe for various Da values according to eq. 3.6 and 3.7 where the pore radius  $b = 5$  nm and  $\zeta = 0.1$ . Hence for a given Da,  $z$  is linearly proportional to Pe and decreases with Da. It is assumed that the pore length exceeds  $z$  and the nanocrystals do not reach the bottom. Even without an applied field, Brownian motion produced a significant degree of adsorption given the concentration of nanocrystals in solution. This process is not described by the Haber model; however, the addition of an electric field did increase the baseline adsorption level.

Figure 3.9: Average depth of penetration of a nanocrystal into a pore vs. Peclet number for various Damkohler numbers assuming a pore radius  $b = 5$  nm and  $\zeta = 0.1$  (low electro-osmosis relative to electrophoresis).

To gain more general insight into how the various factors influence the depth of penetration of a single nanocrystal into the pore, we examine the model further using eq. 3.7 (Table 3.3). The base case corresponds to the parameters in this study as described above. An increase in the pore size by a factor of 3 and 10 raises the average depth,  $z$ , from 50 nm to 160 nm and 640 nm, respectively. Thus, the increase in  $z$  linearly correlates with the increase in  $b$ . Both  $Pe$  and  $Da$  increase linearly with the pore size. The average depth to pore size ratio remains constant. Small changes in the nanocrystal size have little effect on pore penetration as doubling the nanocrystal size increases  $Pe$  and  $Da$  by a factor of two, resulting in opposing effects. The model becomes unreliable as the nanocrystal size begins to approach the pore size, and an overestimation in the average depth into the pore is likely. An increase in either  $\mu$  or  $E$  raises  $v$ , increasing  $Pe$  and resulting in a linear increase in  $z$ . Even for chloroform with  $\epsilon = 4.8$  and thus a relatively small  $\mu$ , the electrophoretic velocity is sufficient to give deep deposition of the nanocrystals, likely because of the small  $\kappa$  and  $Da$ . Higher local deposition rates can be achieved by choosing different ligands during the synthesis of the nanocrystals. With weakly binding ligands and low nanocrystal surface coverage, the nanocrystal–TiO<sub>2</sub> surface interaction would increase. This leads to a higher local deposition rate, an increase in  $Da$ , and a decrease in the nanocrystal penetration depth.

Table 3.3: Kinetic model of average depth of penetration of a single nanocrystal into a cylindrical pore, Peclet number, and Damkohler number as a function of various parameters. (Base case: pore diameter  $b = 10$  nm, particle diameter  $2a = 3.1$  nm, electrophoretic mobility  $\mu = 0.30$  ( $\mu\text{m/s}/(\text{V/cm})$ ), electric field  $E = 17$  kV/cm, local deposition rate  $\kappa = 0.52$  cm/s)

Variable	Peclet (Pe) ( $\times 10^2$ )	Damkohler (Da) ( $\times 10^2$ )	Average depth into pore (z) (nm)
Base case			
	9.6	9.9	50
Pore size			
$b = 30$	29	30	160
$b = 100$	96	99	640
Particle size			
$2a = 2$	6.2	6.4	50
$2a = 6$	18	19	52

$\mu = 0.15$	4.8	9.9	32
$\mu = 0.60$	19	9.9	100
Electric field			
$E = 8.3$	4.8	9.9	25
$E = 33$	19	9.9	100
Local deposition rate const.			
$\kappa = 0.052$	9.6	0.99	490
$\kappa = 5.2$	9.6	99	6.4

For deposition of a large number of nanocrystals from solution into a pore, the single particle model only describes part of the deposition mechanism. If the first particle occupies a site near the top of a nanopillar, the second particle may deposit onto a lower unoccupied site. The nanocrystals adsorbed on the nanopillars are less likely to block the pores than in the case of cylindrical pores. The SE results suggest that the nanocrystals did not tend to contact each other in the lateral direction. Thus the annular region about a layer of nanocrystals on each nanopillar may remain open for further particle diffusion into the pores. In addition, part of the nanocrystal's penetration into the pores may be produced by surface diffusion. The significant adsorption of nanocrystals even without an applied electric field ( $E=0$ ) and the large increase in loading upon doubling the bulk nanocrystal concentration (Table 3.2), to 12 vol% with the field present, are not addressed with the single particle model of Haber. Future work is needed to determine how changes in the binding of the ligand would influence particle-wall interactions and the adsorption and electrophoretic deposition of large numbers of particles versus pore depth.

### 3.5 CONCLUSIONS

Herein, we have demonstrated that 3.1 nm diameter nanocrystals can be deposited electrophoretically into ordered mesoporous  $\text{TiO}_2$  films on ITO/glass electrodes, to reach loadings up to 21 wt.%. The loadings were not limited kinetically in 10 min. relative to 20 hours indicating that the open geometry of the mesochannels is beneficial for diffusion. The nanocrystals are located throughout the mesopores with only a small portion occupying the top planar surface of the film. The relatively small potential drop across the film is beneficial for electrophoretic loading of Au nanocrystals. Both VASE measurements of the anisotropy of the imaginary refractive index,  $k$ , and XPS depth profiling studies indicate that Au nanocrystals are dispersed within the vertically aligned mesopores and distributed throughout the film. Presumably, the high coverage of the strongly-bound thiol ligands on the Au nanocrystals weakens the Au/ $\text{TiO}_2$  interactions.

Therefore, electrophoresis is beneficial for increasing the concentration of nanocrystals near the film, enhancing the thermodynamic driving force for adsorption of Au nanocrystals upon mesoporous TiO<sub>2</sub> with high loadings.

## Chapter 4

### **Hybrid MnO<sub>2</sub>/Disordered Amorphous Mesoporous Carbon Nanocomposites for Electrochemical Pseudocapacitors**

MnO<sub>2</sub>/mesoporous carbon hybrid nanocomposites were synthesized to achieve high values of redox pseudocapacitance at scan rates of 100 mV/s. High resolution transmission electron microscopy (HRTEM) along with energy dispersive X-ray spectroscopy (EDX) demonstrated that ~1 nm thick MnO<sub>2</sub> was conformally distributed throughout the mesoporous carbon structure. HRTEM and X-ray diffraction (XRD) showed formation of MnO<sub>2</sub> nanocrystals with lattice planes corresponding to birnessite. The electrochemical redox pseudocapacitance of these composite materials in aqueous 1 M Na<sub>2</sub>SO<sub>4</sub> electrolyte containing as little as 2 wt % MnO<sub>2</sub> exhibited a high gravimetric MnO<sub>2</sub> pseudocapacitance ( $C_{\text{MnO}_2}$ ) of ~560 F/g<sub>MnO<sub>2</sub></sub>. Even for 30 wt% MnO<sub>2</sub>, a high  $C_{\text{MnO}_2}$  of 137 F/g<sub>MnO<sub>2</sub></sub> was observed at 100 mV/s. Sodium ion diffusion coefficients on the order of 10<sup>-9</sup>–10<sup>-10</sup> cm<sup>2</sup>/s were measured using chronoamperometry. The controlled growth and conformal coating of redox-active MnO<sub>2</sub>/mesoporous carbon composites offers the potential for achieving high power energy storage with low cost materials.

---

The contents of this chapter are being prepared for a manuscript.

## 4.1 INTRODUCTION

Electrochemical capacitors (ECs) are of interest in transportation for starting, acceleration and regenerative braking, in load leveling for smart grids, e.g. those which contain variable energy sources such as windmills and solar cells, and for high clock speed switching in microelectronics.<sup>1-5</sup> ECs offer a very high gravimetric capacitance  $C_g$ , up to 1000 F/g of active material, and power densities  $10^3$ -fold that of batteries; however, the energy densities are typically about 10- to 100-fold smaller. The gravimetric capacitance and consequently, the energy and power densities of ECs may be improved by designing high surface area nanostructured electrodes to enhance charge transfer and ion diffusion.<sup>3, 6</sup>

Electrochemical capacitors may store energy in the electric double layer and by surface redox (Faradaic) reactions.<sup>3, 7</sup> The gravimetric capacitance of a material is directly proportional to the surface area and indirectly proportional to the double layer thickness.<sup>8</sup> The separation of static charges is small, on the order of  $\sim 1$  nm in the electric double layer.<sup>4, 7, 8</sup> For carbon-based electric double layer capacitors (EDLCs), the various allotropes, pore structure, surface area, and graphitic content have been manipulated to tailor the conductivity and  $C_g$ .<sup>9-20</sup> Activated carbons with surface areas between 500 to 2500 m<sup>2</sup>/g typically have a capacitance between 10 to 35 F/g.<sup>8</sup> The electric double layer capacitance may be further increased by either surface functionalization or surface modification with redox-active sites that promote a surface redox pseudocapacitance.<sup>3, 4, 7</sup> Electrode materials for redox pseudocapacitors are typically conductive polymers or transition metal oxides such as ruthenium or manganese oxide. Ruthenium oxide has a high gravimetric pseudocapacitance (as high as 720 F/g<sub>RuO<sub>2</sub></sub>) and high electronic conductivity but is too costly.<sup>21-26</sup> Manganese oxide, a low cost alternative with low toxicity and a high theoretical pseudocapacitance of  $\sim 1370$  F/g<sub>MnO<sub>2</sub></sub>,<sup>27</sup> has been studied extensively for ECs.<sup>27-43</sup> However, to overcome the low electronic conductivity of MnO<sub>2</sub>,<sup>44</sup> it is often mixed with conductive agents such as activated carbon to facilitate electron transfer.

Novel nanocomposite redox pseudocapacitors may be designed by combining conductive carbon materials with a redox-active transition metal oxide to increase the gravimetric capacitance. These metal oxides store electrochemical charge by reversible surface redox reactions and are generally known as pseudocapacitors. In this regard, manganese oxide has been deposited by electrodeposition and electroless deposition on various carbon supports.<sup>44-52</sup> One emerging design strategy is to use mesoporous carbons as scaffolds for MnO<sub>2</sub> where the porous channels in the carbon support provide high surface area, and the conductive carbon scaffold facilitates electronic conductivity. A conformal coating of MnO<sub>2</sub>, no thicker than a few nm, may be grown within the mesopores of the highly conductive carbon to improve the utilization of the pseudocapacitive material.<sup>3, 28</sup> For an MnO<sub>2</sub> loading on the order of 30 wt.%, a uniform coating in ~10 nm mesopores would correspond to a film thickness of ~1 nm. Thin MnO<sub>2</sub> films in mesoporous (2-50 nm) supports with pore sizes of 5-10 nm would be favorable for rapid ion and electron transport to achieve high capacitance. Dong et al. have recently reported MnO<sub>2</sub> embedded in mesoporous carbon pore walls displaying a large C<sub>g</sub>.<sup>45</sup> High C<sub>g</sub> values were also achieved with carbon nanofoam structures that possessed a large pore size distribution and >30 nm MnO<sub>2</sub> particles deposited throughout the support.<sup>44, 48</sup> However, few studies have evaluated charge storage capacities at high rates ( $\geq 100$  mV/s). At higher scan rates, sloping profiles in the current-potential curves are often observed which suggests kinetic limitations due to sluggish ion and electron transport. Furthermore, typical MnO<sub>2</sub> modified carbons display substantial capacity fade and low faradaic efficiencies at high scan rates.

Herein we report the synthesis and characterization of MnO<sub>2</sub> modified disordered mesoporous carbons (MnO<sub>2</sub>/C). The morphology of the MnO<sub>2</sub> on the mesoporous carbon was characterized by scanning electron microscopy (SEM) along with EDX, as well as thermogravimetric analysis (TGA) to determine the MnO<sub>2</sub> content of the nanocomposites. Nitrogen porosimetry was used to characterize the surface area, pore volume, and pore diameter as a function of the MnO<sub>2</sub> content. X-ray diffraction and high resolution transmission electron microscopy were used to determine the crystal structure and size of the MnO<sub>2</sub>. HRTEM EDX was used to establish the dispersibility of the MnO<sub>2</sub>

coating throughout the carbon support. For loadings up to 30 wt% MnO<sub>2</sub>, a ~1 nm thick MnO<sub>2</sub> conformal coating on high surface area disordered mesoporous carbon support with ~8 nm pore size was shown to produce high C<sub>MnO2</sub> up to 137 F/g<sub>MnO2</sub> at a high scan rate of 100 mV/s using cyclic voltammetry. Chronoamperometry measurements were used to estimate an apparent diffusion coefficient of Na<sup>+</sup> of 10<sup>-9</sup>–10<sup>-10</sup> cm<sup>2</sup> s<sup>-1</sup> demonstrating facile ion transport in the nanocomposites. The mechanism for the high pseudocapacitance, especially at high scan rates, is discussed in terms of the morphology of the MnO<sub>2</sub> coating and electrochemical properties of the nanocomposites.

## 4.2 EXPERIMENTAL SECTION

### 4.2.1 Materials

All chemicals were used as received. Sodium sulfate (>99%) and tetrabutylammonium perchlorate (>98%) were acquired from Sigma-Aldrich Cooperation, and potassium permanganate, propylene carbonate (99%), and ethanol (Absolute 200 proof) from Fisher Scientific. High purity deionized water (resistance ~18 MΩ-cm) was used. Argon (research grade, 99.999% purity) was purchased from Praxair.

### 4.2.2 Disordered Amorphous Mesoporous Carbon Synthesis

Disordered mesoporous carbon was prepared via self-assembly of block copolymer and phenolic resin under acidic conditions as described in previous reports.<sup>53, 54</sup> Typically, 16.5 g of resorcinol and 16.5 g of F127 (EO<sub>106</sub>PO<sub>70</sub>EO<sub>106</sub>) were dissolved in 67.5 mL of ethanol and 67.5 mL of HCl aqueous solution (3.0 M). To this solution, 19.5 g of formaldehyde (37 wt % in H<sub>2</sub>O) was added with stirring at room temperature. As the polymerization reaction of resorcinol and formaldehyde proceeded, self-assembly of *in situ* formed phenolic resin and F127 induced a phase separation. The polymer-rich gel phase was collected in the bottom of centrifuge tubes by centrifugation at 9500 rpm for 4 min after the mixture was stirred for 30 min. The gel was re-dissolved in a mixed solvent of 18 g of THF and 12 g of ethanol and the mixture was loaded on a substrate, dried at room temperature overnight, and cured at 80 °C for 24 h. Carbonization was carried out

under N<sub>2</sub> atmosphere at 400 °C for 2 h with a heating rate of 1 °C/min, which was followed by further heat treatment at 850 °C for 3 h with a heating rate of 5 °C/min.

#### **4.2.3 Preparation of MnO<sub>2</sub>/C Composites**

30 mg of disordered mesoporous carbon was mixed with 10 mL of aqueous KMnO<sub>4</sub> solution of known concentration ranging from 0.001 M to 0.1 M and mixed for 5 min. The solution was filtered and washed with DI water to remove un-reacted KMnO<sub>4</sub>. The MnO<sub>2</sub>/C nanocomposite was subsequently calcined in air at 200 °C for 6 hours.

#### **4.2.4 Characterization**

High resolution transmission electron microscopy was performed on a TECNAI G2 F20 X-TWIN microscope in both bright field and scanning transmission electron microscopy (STEM) mode at an accelerating voltage of 200 kV. Drift corrected spectrum mappings were obtained by choosing a reference region in a STEM image to prevent the EDX probe scanning direction from deviating from the area of interest to give enhanced sensitivity and spatial resolution. The EDX mapping was acquired with a dwell time of 3000 ms at any given position, and the map size was 400 positions per nanostructure. The spatial resolution of this technique is ~1 nm. HRTEM images were obtained at the optimum Scherzer defocus. Nanocomposites were deposited from a dilute ethanol solution onto 200 mesh carbon-coated copper TEM grids.

Wide angle X-ray diffraction was performed with samples prepared on a quartz slide using a Bruker-Nonius D8 Advance diffractometer. Samples were scanned for 4 h at a scan rate of 0.3 deg/min with 0.05 deg increments. The average nanocrystal size was estimated from the Scherrer equation using JADE software (by Molecular Diffraction Inc).

Scanning electron microscopy was carried out using a Zeiss Supra 40VP field emission scanning electron microscope. The SEM observation was performed at an accelerating voltage of 10 kV. Energy dispersive X-ray analysis was performed using a LEO 1530 SEM equipped with an IXRF EDX system, the latter operated with a 20 kV electron beam and 60 µm aperture (average counts ~2000 s<sup>-1</sup>). Thermogravimetric analysis was done with a Perkin Elmer TGA 7 instrument. The carbon from the

nanocomposites was burned off by heating the sample to 800 °C and holding the temperature for 30 min.

Nitrogen sorption analysis was performed on a Micromeritics Tristar 3000 analyzer at -196 °C. Prior to measurements, the samples were heated at 150 °C with flowing N<sub>2</sub> at a Micromeritics FlowPrep 060 sample degas system for 4 h. The specific surface area was calculated using the BET method from the nitrogen adsorption data in the relative pressure range ( $P/P_0$ ) of 0.04-0.30. The total pore volume was determined from the amount of N<sub>2</sub> uptake at  $P/P_0 = 0.98$ . Micropore and mesopore areas were calculated using the t-plot method.<sup>55</sup>

Electrochemical measurements were carried out using a CHI 832 electrochemical analyzer (CH instruments Inc.). A three-electrode cell with a Au wire counter electrode and a Hg/Hg<sub>2</sub>SO<sub>4</sub> reference electrode were used. A glassy carbon electrode (0.196 cm<sup>2</sup>, from Pine Instruments) was used as a substrate for the nanocomposite. The glassy carbon electrode was polished with a 0.3 μm followed by a 0.05 μm alumina suspension to give a mirror finish. The MnO<sub>2</sub>/C nanocomposites were mixed with polytetrafluoroethylene (PTFE) in an agate mortar in a 90:10 weight ratio. 1.0 mg of MnO<sub>2</sub>/C was suspended by sonication in 500 μL of ethanol. A total of 15 μL of MnO<sub>2</sub>/C suspension was deposited onto the glassy carbon substrate and dried at room temperature. Electrochemical tests were done in 1 M Na<sub>2</sub>SO<sub>4</sub> at room temperature. Aqueous potentials are referenced vs. Hg/Hg<sub>2</sub>SO<sub>4</sub>. Experiments were also performed in 0.5 M tetrabutylammonium perchlorate (TBAClO<sub>4</sub>) in propylene carbonate (PC) using a custom designed Ag/AgO<sub>x</sub> reference electrode (1.02 V vs. NHE) at a scan rate of 2 mV/s.

### 4.3 RESULTS

Figure 4.1 shows high resolution SEM images of the mesoporous carbon and the MnO<sub>2</sub>/C nanocomposites at various loadings. For the pure carbon (Fig. 4.1a) and 2 wt% MnO<sub>2</sub> (Fig. 4.1b) samples, the mesopores of the carbon are clearly visible. At intermediate loadings of 16 wt% (Fig. 4.1c), the porous structure is more difficult to

Figure 4.1: SEM images of (a) mesoporous carbon and that modified with (b) 2 wt%  $\text{MnO}_2$ , (c) 16 wt%  $\text{MnO}_2$ , and (d) 30 wt%  $\text{MnO}_2$ . Black scale bar is 100 nm.

visualize; however, the formation of short  $\text{MnO}_2$  ribbon structures is noticeable. At the highest loading of 30 wt% (Fig. 4.1d), the ribbon-like structures are considerably more pronounced and are dispersed throughout the porous carbon structure. From XRD analysis, the  $\text{MnO}_2$  is birnessite, which is commonly formed during the reaction between potassium permanganate and carbon.<sup>44, 45, 56</sup>

$\text{MnO}_2/\text{C}$  nanocomposites from 2 wt% to 30 wt% were synthesized, and the amount in the compositions was evaluated by SEM EDX and TGA (Appendix B, Table B.1). The TGA values are slightly higher compared to the SEM EDX results for all samples due to residual amounts of potassium deposited onto the mesoporous carbon substrate during the synthesis. Although the nanocomposites were cleaned by washing with DI water, all of the potassium ions could not be removed. Thus, the  $\text{MnO}_2$  compositions determined by SEM EDX were used to determine the gravimetric capacitance with respect to  $\text{MnO}_2$  content ( $C_{\text{MnO}_2}$ ).

Nitrogen sorption of the nanocomposites provided the BET surface area, pore volume, and the pore size distribution (Table 4.1, Figure 4.2). The nitrogen sorption isotherms are available in Appendix B (Fig. B.1). The mesoporous carbon has a high surface area of  $617 \text{ m}^2/\text{g}$ , a pore volume of  $0.72 \text{ cm}^3/\text{g}$ , and a mean pore diameter centered at 8.4 nm. The micropore (<2 nm) and mesopore (2-50 nm) area of the carbon are  $297 \text{ m}^2/\text{g}$  and  $320 \text{ m}^2/\text{g}$ , respectively. The micropore and mesopore area were calculated using the t-plot method.<sup>55</sup> For the  $\text{MnO}_2/\text{C}$  nanocomposites, the surface area and pore volume decrease with increasing  $\text{MnO}_2$  content as expected. With 8.4 wt%  $\text{MnO}_2$ , there is a marked drop in both surface area and pore volume to  $291 \text{ m}^2/\text{g}$  and  $0.49 \text{ cm}^3/\text{g}$ . These values decrease with  $\text{MnO}_2$  loading up to 30% indicating most of the  $\text{MnO}_2$  coats the mesopores rather than the outermost surface. The decrease in surface area can be attributed to the addition of  $\text{MnO}_2$  throughout the carbon mesopores, the blockage of the micropores, and the higher molecular weight of  $\text{MnO}_2$ . For the  $\text{MnO}_2/\text{C}$  nanocomposites, there is almost no micropore area, according to t-plot method calculations on the sorption isotherms. The introduction of  $\text{MnO}_2$  causes a decrease in the mean pore size and selectively removes the larger pores (Fig. 4.2). The mean pore

Table 4.1: Nitrogen sorption data for mesoporous carbon and MnO<sub>2</sub>/C nanocomposites along with capacitance at 2 mV/s in 1 M Na<sub>2</sub>SO<sub>4</sub>.

MnO <sub>2</sub> content (wt%)	Nitrogen sorption			Capacitance		
	BET surface area (m <sup>2</sup> /g)	Pore volume (cm <sup>3</sup> /g)	Mean pore diameter (nm)	Gravimetric (F/g)	Areal (μF/cm <sup>2</sup> )	Volumetric (F/cm <sup>3</sup> )
0	617	0.72	8.4	28	4.5	24
8.4	291	0.49	7.5	68	23	74

Figure 4.2: Pore size distribution for mesoporous carbon and MnO<sub>2</sub>/C nanocomposites for various compositions. The lines represent best fit Gaussians through the displayed data points.

diameter decreases from 8.4 nm to 7.5 nm with 8.4 wt% MnO<sub>2</sub>. At the 30 wt% loading, the mean pore diameter decreases to 7.0 nm, and a coating thickness of ~0.7 nm is derived using nitrogen porosimetry. A uniform coating thickness through the carbon mesopores can also be estimated on a mass basis from the MnO<sub>2</sub>. Assuming a cylindrical geometry, the coating thickness in an annular region within a pore is

$$t = r_2 - \sqrt{r_2^2 - \left( \frac{wt\%_{MnO_2}}{100 - wt\%_{MnO_2}} \right) \frac{2r_2}{\rho_{MnO_2} A_{Mesopore}}} \quad (4.1)$$

where  $t$  is the thickness,  $r_2$  is carbon pore radius (4.35 nm),  $\rho_{MnO_2}$  is the MnO<sub>2</sub> density (3.4 g/cc), and  $A_{mesopore}$  is the carbon mesopore surface area (320 m<sup>2</sup>/g). For 30 wt% MnO<sub>2</sub>, the coating thickness would be 0.4 nm. Given the large uncertainty from subtracting the mean pore sizes from nitrogen porosimetry before and after MnO<sub>2</sub> addition, the agreement between the two techniques is reasonable. However, this small thickness would indicate the MnO<sub>2</sub> is only an atomic layer thick, which is not conceivable given the deposition method. Most likely the MnO<sub>2</sub> forms domains which are at least a few atomic layers thick, which would give thicknesses of >1 nm.

In Figure 4.3 the XRD patterns for the mesoporous carbon and 21 wt% and 30 wt% MnO<sub>2</sub>/C nanocomposites are shown relative to pure carbon. The large peaks at 23° and 43° indicate the degree of graphitization of the carbon. The broad peaks suggest that the material has some degree of graphitic character from the aromatic carbon precursor, but less than that found for similar mesoporous carbons calcined at higher temperatures.<sup>57, 58</sup> With MnO<sub>2</sub> loaded into the carbon, these peaks diminish and additional small peaks appear at 36.8° and 65.7°. These peaks correspond to the (006) and (119) planes of birnessite (JCPDF #18-0802), respectively.<sup>49, 59</sup> The nanocrystal size of the MnO<sub>2</sub> domains was estimated using the peak at 36.8°. For the 21 wt% and 30 wt% nanocomposites, the nanocrystal sizes were calculated by the Scherrer equation to be 3.8 and 3.5 nm, respectively. From the small size of the peaks, it can be construed that both crystalline and amorphous MnO<sub>2</sub> domains exist within the nanocomposite.

Figure 4.3: XRD of (a) mesoporous carbon, and that modified with (b) 21 wt%  $\text{MnO}_2$ , and (c) 30 wt%  $\text{MnO}_2$  showing birnessite peak present (spectra offset for clarity).

HRTEM was used to characterize the nanostructure of the 30 wt% MnO<sub>2</sub>/C nanocomposite. From the low magnification image in Fig. 4.4a, MnO<sub>2</sub> nanocrystals appear as small dark spots. At higher magnification (Fig. 4.4b), the lattice planes are evident for the MnO<sub>2</sub> nanocrystals, in accord to that seen from XRD. The lattice fringes have a lattice spacing of 2.33 Å, close to the value of 2.44 Å for the (006) planes of birnessite, which were present in the XRD pattern (Fig. 4.2) at 36.8°. This lattice spacing is large enough to accommodate transport of Na<sup>+</sup> ions with a crystal radius of 0.95 Å,<sup>32</sup> The nanocrystal size from the HRTEM image was measured to be 3.6 ± 0.7 nm, in good agreement with the XRD value of 3.5 nm. The dispersion of MnO<sub>2</sub> crystallites in Fig. 4.4a,b is also shown to be consistent with the amount of MnO<sub>2</sub> estimated from TGA and SEM as no large MnO<sub>2</sub> domains are present. The image in Figure 4.4b with a feature size of 3.6 nm is a top down image and does not show the particle thickness. The TEM images also show gaps between the discrete nanodomains. Thus, the thickness of each discrete crystallite would be larger than the thickness of 0.4-0.7 nm from mass based calculations and nitrogen porosimetry. This idea is further supported by an effective spherical particle diameter obtained from XRD measurements of 3.5 nm, which would not be consistent with a thickness of only 0.7 nm. For simplicity, we will refer to the thickness of the MnO<sub>2</sub> domains as ~1 nm.

To supplement the HRTEM images, EDX in STEM mode was performed to show the degree of MnO<sub>2</sub> dispersion throughout the nanocomposite (Fig. 4.4c). STEM-EDX mapping enables imaging the elemental distribution in a fine area with its high-resolution, and the specimen-drift auto-compensation system gives enhanced sensitivity and spatial resolution. In STEM mode, the image contrast is proportional to the mass density times the atomic number squared. Therefore Mn will give a much higher intensity than C since the ratio of the atomic numbers squared is 20. From Fig. 4.4c, the small bright white dots correspond to the MnO<sub>2</sub> nanocrystals. In Fig. 4.4d-f, the K-line energies of the Mn, O, and C intensities are given in red, green, and blue, respectively. The red intensity is visible across the entire nanocomposite and indicates the Mn is uniformly distributed throughout the carbon support. Comparison of the STEM image in Fig. 4.4c with the EDX shows a strong correspondence between the MnO<sub>2</sub> nanocrystals

Figure 4.4: HRTEM images and EDX of 30 wt%  $\text{MnO}_2/\text{C}$  nanocomposite: (a) Low mag, (b) high mag, (c) STEM, and STEM-EDX intensities for (d) Mn, (e) O, (f) C.

and the strong red intensities from Mn and green intensities from O. Hence, the EDX mapping of the MnO<sub>2</sub>/C nanocomposite shows deposition of MnO<sub>2</sub> crystallites throughout the support.

Cyclic voltammetry (CV) was utilized to estimate the pseudocapacitive properties of the MnO<sub>2</sub>/C nanocomposites as shown in Figure 4.5 between 0.4 to -0.4 V at a both 2 and 100 mV/s in 1 M Na<sub>2</sub>SO<sub>4</sub>. The profiles are relatively flat and rectangular which is typical for electrochemical double-layer capacitors as well as for some redox pseudocapacitors composed of MnO<sub>2</sub>.<sup>3, 5</sup> At 2 mV/s with a loading of 2 wt% MnO<sub>2</sub>, the capacitance increases ~40% compared to the mesoporous carbon. With higher loadings of 16 wt% and 30 wt%, the flat profile is still evident, which indicates the conductivity remains sufficient at this low scan rate even with a large amount of MnO<sub>2</sub> material. At the higher scan rate (100 mV/s), the flat profiles are still present indicating both good ion transport and conductivity for the nanocomposites. Figure 4.6 shows the gravimetric capacitance values at both 2 and 100 mV/s with respect to MnO<sub>2</sub> mass (Fig. 4.6a) and total composite mass (MnO<sub>2</sub> + carbon) (Fig. 4.6b). The total gravimetric capacitance  $C_g$  values were calculated with the following equation

$$C_g = (\Delta I/2)/(vm) \quad (4.2)$$

where  $\Delta I$  is the current difference at 0 V in the two different scanning directions,  $v$  is the scan rate, and  $m$  is the mass of active material. A maximum  $C_{MnO_2}$  of 560 F/g<sub>MnO<sub>2</sub></sub> was measured for the 2 wt% MnO<sub>2</sub>/C nanocomposite and decreases with higher loadings of MnO<sub>2</sub> for both scan rates. At 2 mV/s, the  $C_{MnO_2}$  decreased almost linearly up to 21 wt% MnO<sub>2</sub>; however, it remained at ~200 F/g<sub>MnO<sub>2</sub></sub> for 30 wt%. At 100 mV/s, the behavior changed as the  $C_{MnO_2}$  appeared to level off at 16 wt% with a final  $C_{MnO_2}$  of 137 F/g<sub>MnO<sub>2</sub></sub> at 30 wt%. At 2 mV/s, the  $C_g$  (Fig. 4.6b) increased sharply at lower mass loadings and then leveled off. The maximum  $C_g$  was 79 F/g at 30 wt%, an increase of almost threefold compared to the unmodified mesoporous carbon. At 100 mV/s this increase was similar. At the high scan rate, the  $C_g$  is nearly linear in the loading of MnO<sub>2</sub> over the entire range (Fig. 4.6b). For the 30 wt% MnO<sub>2</sub>/C nanocomposite, there is a 32% drop in  $C_g$  with over a 50-fold change in the scan rate.

Figure 4.5: Cyclic voltammetry of the mesoporous carbon and MnO<sub>2</sub>/C nanocomposite for various compositions at (a) 2 mV/s and (b) 100 mV/s in 1 M Na<sub>2</sub>SO<sub>4</sub>.

Figure 4.6: Gravimetric capacitance values for MnO<sub>2</sub>/C nanocomposites at 2 mV/s and 100 mV/s in 1 M Na<sub>2</sub>SO<sub>4</sub> based on (a) MnO<sub>2</sub> mass (b) total mass.

The maximum energy density ( $E_{\max}$ ) can be calculated from the  $C_g$ ,

$$E_{\max} = \frac{1}{2}C_{\text{cell}}V^2 \quad (4.3)$$

where  $V$  is the potential window and taken to be a maximum of 1.2 V, the breakdown of water, and  $C_{\text{cell}}$  is the device capacitance ( $C_g/2$ ). The highest energy density is for the 30 wt%  $\text{MnO}_2/\text{C}$  sample, which exhibits the highest  $C_g$ . At 2 and 100 mV/s, the maximum energy densities were 7.9 and 5.4 Wh/kg, respectively. These values fall within typical pseudoapacitor energy densities (1-10 Wh/kg).<sup>8</sup>

Using the nitrogen sorption data for the  $\text{MnO}_2/\text{C}$  nanocomposites, the areal and volumetric capacitances are calculated at 2 mV/s (Table 4.1). With a higher  $\text{MnO}_2$  content, the BET surface area decreases; accordingly, the areal capacitance increases by almost an order of magnitude from 4.5  $\mu\text{F}/\text{cm}^2$  for the mesoporous carbon to 42  $\mu\text{F}/\text{cm}^2$  for the 30 wt%  $\text{MnO}_2/\text{C}$  nanocomposite. This increase reflects the greater storage capacity of the redox pseudocapacitance of  $\text{MnO}_2$  reaction relative to EDLC of carbon. From the pore volume, the volumetric capacitance can also be calculated and increases similarly to the  $C_g$ . For the mesoporous carbon the volumetric capacitance is 24  $\text{F}/\text{cm}^3$ , and with 30 wt%  $\text{MnO}_2/\text{C}$ , it increases by 450% to 108  $\text{F}/\text{cm}^3$ .

Chronoamperometry was used to measure the apparent diffusion coefficient (or ambipolar diffusion coefficient)  $D$ , which is composed of both the ionic and electronic diffusion. Estimation of  $D$  includes an intrinsic thermodynamic enhancement factor, which can be expressed as the product of the transference number of the electron and the ratio of the change in ion activity to change in ion concentration.<sup>60</sup> With increasing  $\text{MnO}_2$  content,  $D$  decreases for both insertion and deinsertion (Fig. 4.7). The bare carbon support has a high insertion value of  $7.4 \times 10^{-9} \text{ cm}^2/\text{s}$  and a slightly lower deinsertion value of  $5.0 \times 10^{-9} \text{ cm}^2/\text{s}$ . These values are several orders of magnitude slower than for  $\text{Na}^+$  diffusion through bulk solution ( $\sim 10^{-5} \text{ cm}^2/\text{s}$ ). With the addition of  $\text{MnO}_2$  into the pores,  $D$  begins to decrease. At 30 wt%  $\text{MnO}_2$ ,  $D$  drops by an order of magnitude to  $8.0 \times 10^{-10}$  and  $4.7 \times 10^{-10} \text{ cm}^2/\text{s}$  for insertion and deinsertion, respectively. The lower  $D$  at high  $\text{MnO}_2$  content results predominately from ionic diffusion into the  $\text{MnO}_2$  layer.

Figure 4.7: Apparent diffusion coefficient values for insertion and deinsertion of Na<sup>+</sup> in MnO<sub>2</sub>/C nanocomposites in 1 M Na<sub>2</sub>SO<sub>4</sub>.

The nanocomposite materials were also tested in propylene carbonate (PC) with tetrabutylammonium perchlorate, TBAClO<sub>4</sub>, as the electrolyte (Appendix B, Fig. B.2, Table B.3). The large cation size of  $\sim 9 \text{ \AA}$ <sup>61</sup> prevents entrance into the MnO<sub>2</sub> lattice. Consequently, contributions to the capacitance due faradaic pseudocapacitance are insignificant in nonaqueous solvents. Therefore, these experiments provide a means for estimating contributions due to double-layer charging processes.<sup>49</sup> The C<sub>g</sub> is similar for all of the nanocomposites tested ( $\sim 26 \text{ F/g}$ ) and about the same as for mesoporous carbon (28 F/g) in the aqueous electrolyte, as expected. The current-potential curves at 2 mV/s were also flat rectangular profiles indicating satisfactory electronic conductivity (Appendix B, Fig. B.2) similar to Fig. 4.5 with 1 M Na<sub>2</sub>SO<sub>4</sub>. Together, these results confirm that no pseudocapacitive contribution was present, and the electric double-layer capacitance was constant with MnO<sub>2</sub> content. These measurements indicate that there is very little change in the electrochemically active surface area of the carbon after modification with MnO<sub>2</sub>.<sup>49</sup> Hence, the additional capacitance found in Na<sub>2</sub>SO<sub>4</sub> was due to the faradaic contribution involving MnO<sub>2</sub>.

#### 4.4 DISCUSSION

The redox charge storage mechanism in MnO<sub>2</sub> occurs via insertion/deinsertion of sodium ions

or by surface adsorption via

Both mechanisms are sufficiently fast to yield reasonable power densities.<sup>3</sup> With the inclusion of MnO<sub>2</sub> inside of the mesopores, the surface area per mass of MnO<sub>2</sub> decreases due to the decrease in pore diameter, micropore blockage, and the heavier MnO<sub>2</sub>. However, even with this slight decrease in surface area, the contribution from the double-layer capacitance remains constant as measured with the large tetrabutylammonium cation, TBA<sup>+</sup>, which does not penetrate MnO<sub>2</sub> and contribute to pseudocapacitance. For

all the samples, the gravimetric capacitance decreased with scan rate indicating limits in electron and/or ion transport.

The decrease in  $C_{\text{MnO}_2}$  with higher  $\text{MnO}_2$  content (Fig. 4.6a) can be explained in terms of the EDLC and the pseudocapacitance contributions. At low  $\text{MnO}_2$  content, most of the  $\text{MnO}_2$  is present as a “surface oxide”, and the surface Faradaic contribution (rxn. 4.5) dominates. With more  $\text{MnO}_2$  incorporated into the composite, the thickness of the film increases, and the classical diffusion based insertion/deinsertion mechanism becomes more important. Here the  $C_{\text{MnO}_2}$  decreases, indicating a smaller fraction of  $\text{MnO}_2$  is fully utilized. Perhaps most of the surface sites (rxn. 4.5) are utilized, but only a small fraction of the underlying more bulk-like sites (rxn. 4.4) are utilized at faster scan rates. Assuming the smallest diffusion coefficient  $D$  of  $4.7 \times 10^{-10} \text{ cm}^2/\text{s}$  and a short time of 0.01 s, the diffusion length  $L = (D\tau)^{1/2}$  would be 22 nm. Hence diffusion into the ~1 nm thick  $\text{MnO}_2$  coating should be facile, yet the capacitance fades at high scan rates. Thus, this loss is likely influenced significantly by limitations in electronic conductivity of the carbon support, which is not surprising given the less graphitic character of this mesoporous carbon relative to other forms of carbon. For  $\text{MnO}_2/\text{C}$  nanocomposites utilizing more graphitic carbons, presumably ~1 nm  $\text{MnO}_2$  coatings would be more fully utilized and display higher faradaic efficiencies at high scan rates.

The choice of pore size for the carbon support is an important factor for influencing electrolyte transport and  $\text{MnO}_2$  utilization. For a given  $\text{MnO}_2$  loading, the  $\text{MnO}_2$  thickness can be estimated for infinitely long cylindrical pores from the equation

$$\frac{r_2}{r_1} = \sqrt{\frac{1-\phi}{1-\frac{1}{\varepsilon}\phi}} \quad (4.6)$$

where  $r_2$  is the carbon pore radius,  $r_1$  is the pore radius after coating with  $\text{MnO}_2$ ,  $\varepsilon$  is the carbon porosity, and  $\phi$  is the volume fraction  $\text{MnO}_2$  inside the pore. Assuming a carbon porosity of 50% and  $\text{MnO}_2$  loading of 30 wt. %, the  $\text{MnO}_2$  thickness would be 0.16, 0.8, and 4.0 nm for pore sizes of 2, 10, and 50 nm. Micropores (<2 nm) would be unfavorable because of high solution resistance and possible pore blockage.<sup>9</sup> For macropores (>50 nm), the film thickness becomes too large leading to poor conductivity

in MnO<sub>2</sub>, especially for larger values of  $\phi$ . Hence, mesopores (2-50 nm) are a desirable geometry for supporting MnO<sub>2</sub> domains, as shown in the current study for a pore size of ~10 nm and a MnO<sub>2</sub> thickness of ~1 nm, to facilitate rapid ion and electron transport.

Table 4.2 provides a comparison between this study and two other recent reports of carbon-based nanocomposites with similar MnO<sub>2</sub> loadings. For ordered mesoporous carbon modified using KMnO<sub>4</sub>, amorphous MnO<sub>2</sub> particles were embedded inside of the carbon walls.<sup>45</sup> The CV curves had sloping profiles, which increased with MnO<sub>2</sub> content, indicating a larger electrolyte and ohmic resistance from the non-conducting MnO<sub>2</sub> even at a low scan rate. The authors measured the gravimetric capacitance at the maximum possible current difference between anodic and cathodic scans, rather than in the middle of the potential range in the CV profiles as is the common benchmark.<sup>45</sup> Re-analysis of the data in Dong et al. yields a specific capacitance in 2 M KCl of 95 F/g (149 F/g<sub>MnO2</sub>, 11  $\mu$ F/cm<sup>2</sup>) at 9.4 wt% MnO<sub>2</sub> and 110 F/g (167 F/g<sub>MnO2</sub>, 16  $\mu$ F/cm<sup>2</sup>) at 26 wt% MnO<sub>2</sub>. Although the  $C_g$  is higher compared to the present study, the  $C_{MnO2}$  is much lower. At 8.4 wt%, the  $C_{MnO2}$  of 507 F/g<sub>MnO2</sub> is threefold higher in the present study. At 30 wt%, the  $C_{MnO2}$  is still slightly higher at 199 F/g<sub>MnO2</sub> than for composites with 26 wt% MnO<sub>2</sub> reported by Dong et al. The ordered carbon pores in Dong et al. may limit the ion diffusion and increase the electrolyte resistance, as suggested by the sloping CV curves. The areal capacitance is also two times higher in the present study. Perhaps a composite displaying a more disordered porous system with many transport pathways facilitates far more facile ion transport<sup>63</sup> and leads to flatter CV profiles, as acquired in the present study (Fig. 4.5).

Carbon nanofoams with a 3D disordered pore structure (pore size distribution from 1 to 100 nm) have also been used as supports.<sup>44, 48, 62</sup> The foams contained MnO<sub>2</sub> particles from 10 to 30 nm. A  $C_g$  in 1 M Na<sub>2</sub>SO<sub>4</sub> of 74 F/g (187 F/g<sub>MnO2</sub>, 20  $\mu$ F/cm<sup>2</sup>, 49 F/cm<sup>3</sup>) was obtained at 28 wt% MnO<sub>2</sub> (Table 4.2) at low scan rates, comparable to those in the present study. However, the estimated volumetric and areal capacitances at low scan rates in the present study were twice as large presumably due to a more optimal pore size and uniform pore size distribution.

MnO<sub>2</sub> on highly conductive multi-walled carbon nanotube (CNT) composites have been investigated.<sup>52</sup> A loading of ~55 wt% MnO<sub>2</sub> produced ~6 nm coating with an  $\epsilon$ -MnO<sub>2</sub> crystallinity. At 2 mV/s with 0.5 M Na<sub>2</sub>SO<sub>4</sub>, the C<sub>g</sub> and C<sub>MnO<sub>2</sub></sub> were high at 205 F/g and 350 F/g<sub>MnO<sub>2</sub></sub>. However, at 100 mV/s, they dropped to 25 F/g and 37 F/g<sub>MnO<sub>2</sub></sub>. The C<sub>g</sub> and C<sub>MnO<sub>2</sub></sub> of 54 F/g and 137 F/g<sub>MnO<sub>2</sub></sub> in the present study were more than twofold larger, indicating a much smaller decrease as the scan rate increased. The CVs for the CNT composites have large sloping profiles suggesting ohmic resistance from the thick 6 nm MnO<sub>2</sub> coatings on the CNTs. The ~1 nm thick MnO<sub>2</sub> nanodomains in the current study result in flatter profiles for the CVs and higher capacitances at high scan rates.

In the present study, soft-templated disordered mesoporous carbon was synthesized and coated with both amorphous and crystalline MnO<sub>2</sub> domains. The soft-template synthesis strategy for carbon is advantageous in that a sacrificial template is not required and excess synthesis and activation steps can be avoided. The narrow pore size distribution used in this study centered at 8.4 nm allows for enough space for MnO<sub>2</sub> domains to form with a thickness ~1 nm throughout the carbon structure. As seen in the pore size distribution data for 30 wt% MnO<sub>2</sub>/C nanocomposites (Fig. 4.2), the pore size is ~7.0 nm, a decrease of only ~17%, which still provides enough open porosity to facilitate facile ion transport. The 3D pore interconnectivity also aids in decreasing the solution resistance by providing multiple pathways for ion transport.<sup>63</sup> The degree of crystallinity of the MnO<sub>2</sub> domains can also be influential factors as amorphous areas are still present. With large interlayer spacings possible from various MnO<sub>2</sub> polymorphs, an improved crystal structure can possibly lead to higher pseudocapacitance.<sup>32</sup> The graphitic nature of the mesoporous carbon can influence the electronic conductivity and the MnO<sub>2</sub> coating process. For our materials the disordered mesoporous carbon is fairly amorphous as evidenced by broad XRD peaks, suggesting small graphitic domains (Fig. 4.3). It is well known that more graphitic carbons are more electronically conductive.<sup>54, 58</sup> In addition, graphitic carbon supports can be functionalized in a controlled matter, e.g. by oxidation, to promote wetting and deposition of MnO<sub>2</sub> at edge plane sites,<sup>64</sup> which is more difficult to achieve with amorphous carbons. Both graphitization of the carbon substrate and use of thin MnO<sub>2</sub> layers may be expected to lead to decreased ohmic resistance and higher

energy densities for high rate applications. Further modification in the design of the nanocomposites can lead to improvements in the energy density approaching those of batteries.

#### 4.5 CONCLUSIONS

Herein, we have demonstrated an enhancement in  $C_g$  of almost threefold for  $\text{MnO}_2/\text{C}$  nanocomposites with 30 wt%  $\text{MnO}_2$  compared to the bare mesoporous carbon support. The deposition of redox-active  $\text{MnO}_2$  coatings upon a nanostructured mesoporous carbon support augments the double-layer capacitance with substantial redox pseudocapacitance. The thin nanodomains with a thickness of  $\sim 1$  nm within the support allow for a high pseudocapacitance, while preserving open and available disordered pores that facilitate ion transport. At high scan rates, the total gravimetric capacitance exhibited a linear increase with  $\text{MnO}_2$  content, whereas the  $C_{\text{MnO}_2}$  decreased and leveled off. Even for 30 wt%  $\text{MnO}_2$ , a high  $C_{\text{MnO}_2}$  of 137 F/g $_{\text{MnO}_2}$  was observed at 100 mV/s, consistent with a relatively small change in the diffusion coefficient with loading according to chronoamperometry. The leveling off in  $C_{\text{MnO}_2}$  with scan rate indicates that the  $\text{Na}^+$  continues to diffuse throughout a significant fraction of the  $\text{MnO}_2$  domains. The high  $C_{\text{MnO}_2}$  of these nanodomains at high scan rates is a significant advancement towards the ultimate goal of high energy and power densities for electrochemical capacitors with thin conformal coatings of  $\text{MnO}_2$ .

## Chapter 5

### High Specific Capacity and High Rate MnO<sub>2</sub>/Graphitic Mesoporous Carbon Electrochemical Capacitors

Nanocomposites composed of MnO<sub>2</sub> and graphitic disordered mesoporous carbon (MnO<sub>2</sub>/C) were synthesized for high specific capacitance or redox pseudocapacitance ( $C_{\text{MnO}_2}$ ) at high rates of 200 mV/s. High resolution transmission electron microscopy (HRTEM) with energy dispersive X-ray spectroscopy (EDX) demonstrated that MnO<sub>2</sub> nanodomains were highly dispersed throughout the mesoporous carbon structure. According to HRTEM and X-ray diffraction (XRD), the MnO<sub>2</sub> domains are shown to be primarily amorphous, with a thickness of  $\sim 1$  nm from nitrogen porosimetry. For these composites in aqueous 1 M Na<sub>2</sub>SO<sub>4</sub> electrolyte,  $C_{\text{MnO}_2}$  reached 500 F/g<sub>MnO<sub>2</sub></sub> at 2 mV/s for 8.8 wt% MnO<sub>2</sub>. A capacitance fade of only 20% over a 100-fold change in scan rate was observed for a high loading of 35 wt% MnO<sub>2</sub> with a  $C_{\text{MnO}_2}$  of 310 F/g<sub>MnO<sub>2</sub></sub> at the highest scan rate of 200 mV/s. The 35 wt% MnO<sub>2</sub>/C exhibited a high volumetric capacitance of 400 F/cm<sup>3</sup>. The relaxation time constants of  $<1$  s were unusually short because of the nanocomposite architecture and high conductivity. The high electronic conductivity of the graphitic 3D disordered mesoporous carbon support in conjunction with the  $\sim 1$  nm thick MnO<sub>2</sub> nanodomains facilitate rapid electron and ion transport offering the potential of improved high power density energy storage pseudocapacitors.

---

The contents of this chapter are being prepared for a manuscript.

## 5.1 INTRODUCTION

Electrochemical double-layer capacitors (EDLCs), pseudocapacitors, and supercapacitors are commonly used monikers for a class of electrochemical energy-storage devices already used in digital cameras, cell phones, circuit boards, industrial equipment, and transportation vehicles.<sup>1, 2</sup> Electrochemical capacitors can be grouped into two categories: an electrochemical double-layer capacitor and a redox pseudocapacitor (otherwise known as a supercapacitor). EDLCs store electrical energy from double-layer capacitance generated by charge separation at the interface between a solid electrode and a liquid electrolyte. High surface area carbon materials such as activated carbon, carbon nanotubes (CNTs), and carbon aerogels/foams are commonly used as electrode materials for EDLCs. In contrast, redox pseudocapacitors store electrical energy from fast and electrochemically reversible faradaic redox reactions occurring at or near a solid electrode. In this class, electrode materials for pseudocapacitors are typically conducting polymers such as polyaniline and transition metal oxides such as  $\text{RuO}_2$  and  $\text{MnO}_2$ . The higher specific power of electrochemical capacitors is ideally suited for the rapid storage and release of energy relative to most batteries, whereas their specific energy is somewhat lower. Through appropriate materials and cell design, both the specific energy and specific power ranges can span several orders of magnitude. Thus pseudocapacitors are attractive for energy storage and supply either alone or in combination with batteries in hybrid systems.<sup>3</sup> The characteristic combination of high power capability and good specific energy allows pseudocapacitors to occupy a functional position between batteries and conventional capacitors, especially with regard to the advanced development of hybrid electric vehicles and load leveling smart grids.<sup>4, 5</sup> With improved design of material architectures, the gap between pseudocapacitors and batteries can be narrowed resulting in cheaper, longer-lasting materials<sup>3, 6, 7</sup>

For  $\text{MnO}_2$ , a redox-active material, high gravimetric pseudocapacitances around 700 F/g<sub>MnO2</sub> on nickel foil at a scan rate of 50 mV/s<sup>8</sup> or a low current density of 160  $\mu\text{A}/\text{cm}^2$ <sup>29</sup> were reported for thin films on conductive planar substrates. An atypically large

$C_{\text{MnO}_2}$  of  $\sim 1380 \text{ F/g}_{\text{MnO}_2}$  at a low scan rate was reported for 420 nm agglomerated  $\text{MnO}_2$  porous particles deposited on highly conductive platinum foil.<sup>10</sup> This value is essentially the theoretical limit of  $1370 \text{ F/g}_{\text{MnO}_2}$  for a redox reaction with a single electron per manganese atom.<sup>10</sup> However, the  $C_{\text{MnO}_2}$  is known to drop off markedly when sub-10 nm  $\text{MnO}_2$  domains are supported on high surface area porous carbon, that has much lower conductivity, relative to Pt.<sup>11</sup> The properties of a carbon support can be tailored to increase the capacitance by changing the surface area, pore structure, and electronic conductivity.<sup>3, 12-19</sup> The gravimetric capacitance in an EDLC is directly proportional to the accessible surface area. For carbon EDLCs, the gravimetric capacitance reaches values of  $250 \text{ F/g}$  for high surface areas on the order of  $2000 \text{ m}^2/\text{g}$ .<sup>12</sup> The high surface area results mainly from micropores ( $<2 \text{ nm}$ ) with little contribution from mesopores ( $2\text{-}50 \text{ nm}$ ) and macropores ( $>50 \text{ nm}$ ). However, limited ion transport through micropores<sup>13, 15</sup> lowers the capacitance at high rates.

The energy density of a pseudocapacitor may be enhanced with mesoporous materials with pore sizes of  $5\text{-}10 \text{ nm}$  that favor rapid ion transport and also offer relatively high surface areas on the order of  $300 \text{ m}^2/\text{g}$ .<sup>6, 13</sup> Furthermore, the pore size is sufficiently large for deposition of a thin conformal coating of a pseudocapacitive material<sup>20-23</sup> with a thickness on the order of  $1 \text{ nm}$ . High  $C_{\text{MnO}_2}$  were achieved at  $50 \text{ mV/s}$  but were much lower than the values at  $5 \text{ mV/s}$ .<sup>22</sup> In the previous chapter, disordered mesoporous carbon composites with highly dispersed  $\text{MnO}_2$  at loadings of  $30 \text{ wt}\%$  were formed and achieved a high  $C_{\text{MnO}_2}$  of  $137 \text{ F/g}_{\text{MnO}_2}$  at a high scan rate of  $100 \text{ mV/s}$ . A high volumetric capacitance of  $110 \text{ F/cm}^3$  was also attained as a consequence of the high loading and high surface area to volume support. Despite the relatively high utilization of the  $\text{MnO}_2$ , the  $C_{\text{MnO}_2}$  was limited by the low electronic conductivity of the carbon support, given the low graphitic content produced by heat treatment at only at  $850^\circ\text{C}$ . A higher electronic conductivity would accelerate electron transfer throughout the carbon support to the  $\text{MnO}_2$  domains to compliment rapid ion diffusion in the pores and raise the  $C_{\text{MnO}_2}$ .

For mesoporous carbons graphitized at only  $\sim 850^\circ\text{C}$ , the electronic conductivity is low  $\sim 0.3 \text{ S/cm}$ .<sup>16, 24</sup> In contrast, electronic conductivities can reach  $4.2 \text{ S/cm}$ <sup>16</sup> to  $330$

S/cm<sup>24</sup> for higher levels of graphitization with heat treatments  $\geq 2300$  °C. These materials are composed of carbon atoms sp<sup>2</sup> hybridized in stacked, highly ordered hexagonal rings.<sup>25</sup> EDLCs composed of 3D aperiodic hierarchical porous (1-100 nm) graphitic carbon materials give a capacitance fade of only ~10% going from 5 to 100 mV/s.<sup>18</sup> However, upon deposition of a redox-active metal oxide into this type of architecture, the smaller pores in the broad pore size distribution support ranging from 1-100 nm may become blocked, and the surface area may be limited for conformal coating for the larger pores. Alternatively, CNT electrodes have received a lot of attention as they possess uniform diameters of tens of nanometers, are highly electronically conductive, and have mesoporous character.<sup>14, 15</sup> Carbons of this type with 3D interpenetrating void and solid structures comprising ionic and electronic conductive networks are more optimal for use as pseudocapacitor electrodes. Therefore, graphitic carbon supports with a high surface area, mesopores, and high electronic conductivity would be more beneficial for improving the electrochemical utilization of the redox-active metal oxide or polymer as a pseudocapacitive material. Using a soft-template strategy, this architecture can be designed readily to give high surface area mesoporous carbon supports with uniform pore size distributions and high electronic conductivities.<sup>26</sup>

Herein we report high MnO<sub>2</sub> pseudocapacitance at high rates by depositing MnO<sub>2</sub> nanodomains into highly graphitic mesoporous carbon with high electronic conductivity. The synthesis of the 3D disordered pores with a soft-template leads to thicker walls than with typical hard templates. The thicker walls enable a higher electronic conductivity, for example, ~330 S/cm for heat treatment at 2600 °C.<sup>24</sup> High loadings of MnO<sub>2</sub> to 35 wt% with excellent dispersion are achieved by electroless deposition inside the mesoporous carbon support with ~8 nm pores. The as-synthesized graphitic carbon surface is hydrophobic and impedes wetting of the aqueous precursor, limiting loadings to <1 wt%. The carbon was oxidized to increase the hydrophilicity to promote wetting and deposition of MnO<sub>2</sub> at edge plane sites. The high support electronic conductivity in conjunction with the 3D high surface area disordered mesopores, which favor high MnO<sub>2</sub> loading and rapid ion transport, are shown to enable high C<sub>MnO2</sub>, even at very high scan rates of 200 mV/s. A high C<sub>MnO2</sub> of 310 F/g<sub>MnO2</sub> is achieved even for 35 wt% MnO<sub>2</sub> at

200 mV/s. The structure and composition of the nanocomposites is characterized using scanning electron microscopy, X-ray diffraction, nitrogen porosimetry, and high resolution transmission electron microscopy with energy dispersive spectroscopy. XRD and HRTEM are used to probe the degree of crystallinity of the MnO<sub>2</sub>. HRTEM EDX shows the MnO<sub>2</sub> is well dispersed throughout the carbon support. Electrochemical impedance spectroscopy is utilized to evaluate the charge transfer resistance, diffusional resistance of the ions through the pores of the composite, and the dielectric relaxation time constant, which provides a relative indication of the power density.<sup>21</sup>

## **5.2 EXPERIMENTAL SECTION**

### **5.2.1 Materials**

All chemicals were used as received. Sodium sulfate (>99%) was acquired from Sigma-Aldrich Cooperation, and potassium permanganate, and ethanol (Absolute 200 proof) from Fisher Scientific. High purity deionized water (resistance ~18 MΩ-cm) was used. Argon (research grade, 99.999% purity) was purchased from Praxair.

### **5.2.2 Graphitic Mesoporous Carbon Synthesis**

Disordered mesoporous carbon was prepared via self-assembly of block copolymer and phenolic resin under acidic conditions as described in previous reports.<sup>27, 28</sup> Typically, 16.5 g of resorcinol and 16.5 g of F127 (EO<sub>106</sub>PO<sub>70</sub>EO<sub>106</sub>) were dissolved in 67.5 mL of ethanol and 67.5 mL of HCl aqueous solution (3.0 M). To this solution, 19.5 g of formaldehyde (37 wt % in H<sub>2</sub>O) was added with stirring at room temperature. As the polymerization reaction of resorcinol and formaldehyde proceeded, self-assembly of *in situ* formed phenolic resin and F127 induced a phase separation. The polymer-rich gel phase was collected in the bottom of centrifuge tubes by centrifugation at 9500 rpm for 4 min after the mixture was stirred for 30 min. The gel was re-dissolved in a mixed solvent of 18 g of THF and 12 g of ethanol and the mixture was loaded on a substrate, dried at room temperature overnight, and cured at 80 °C for 24 h. Carbonization was carried out

under N<sub>2</sub> atmosphere at 400 °C for 2 h with a heating rate of 1 °C/min, which was followed by further heat treatment at 2600 °C for 3 h with a heating rate of 5 °C/min.

### **5.2.3 Preparation of Oxidized Graphitic Mesoporous Carbon**

100 mg of graphitic mesoporous carbon was mixed with 20 mL of 5 M HNO<sub>3</sub>. The solution was stirred and refluxed overnight. The oxidized graphitic mesoporous carbon was filtered, washed with copious amounts of DI H<sub>2</sub>O, and dried at 100 °C.

### **5.2.4 Preparation of MnO<sub>2</sub>/C Composites**

20 mg of oxidized graphitic mesoporous carbon (OGMC) was mixed with 10 mL of aqueous 0.1 M KMnO<sub>4</sub> solution in neutral pH for various times from 10 min to 24 hrs. The solution was filtered and washed with DI water to removed un-reacted KMnO<sub>4</sub>. The MnO<sub>2</sub>/C nanocomposite was subsequently calcined at 100 °C in air overnight.

### **5.2.5 Characterization**

High Resolution Transmission Electron Microscopy was performed on a TECNAI G2 F20 X-TWIN microscope in both bright field and scanning transmission electron microscopy (STEM) mode at an accelerating voltage of 200 kV. Drift corrected spectrum mappings were obtained by choosing a reference region in a STEM image to prevent the EDX probe scanning direction from deviating from the area of interest. The EDX mapping was acquired with a dwell time of 3000 ms at any given position, and the map size was 400 positions per nanostructure. The spatial resolution of this technique was close to 1 nm. HRTEM images were obtained at the optimum Scherzer defocus. Nanocomposites were deposited from a dilute ethanol solution onto 200 mesh carbon-coated copper TEM grids.

Wide angle X-ray diffraction was performed with samples prepared on a quartz slide using a Bruker-Nonius D8 Advance diffractometer. Samples were analyzed in 0.05 deg increments with a dwell time of 10 s. The average nanocrystal size was estimated from the Scherrer equation using JADE software (by Molecular Diffraction Inc).

Scanning electron microscopy (SEM) was carried out using a Zeiss Supra 40VP field emission scanning electron microscope. The SEM observation was performed at an

accelerating voltage of 10 kV. The MnO<sub>2</sub> content of the nanocomposites was determined using energy dispersive X-ray analysis on a LEO 1530 SEM equipped with an IXRF EDX system, the latter operated with a 20 kV electron beam and 60  $\mu$ m aperture (average counts  $\sim$ 2000 s<sup>-1</sup>).

Nitrogen sorption analysis was performed on a high-speed surface area BET analyzer (NOVA 2000, Quantachrome Instruments, Boynton Beach, FL) at a temperature of 77 K. Prior to measurements, the samples were degassed overnight. The specific surface area was calculated using the BET method from the nitrogen adsorption data in the relative pressure range ( $P/P_0$ ) of 0.05-0.30. The total pore volume was determined from the amount of N<sub>2</sub> uptake at  $P/P_0 = 0.95$ . Pore size distributions were analyzed using the adsorption branch of the isotherm.

Cyclic voltammetry was carried out using a CHI 832A electrochemical analyzer (CH Instruments Inc.). A three-electrode cell with a Au wire counter electrode and a Hg/Hg<sub>2</sub>SO<sub>4</sub> reference electrode was used. A glassy carbon electrode (0.196 cm<sup>2</sup>, from Pine Instruments) was used as a substrate for the MnO<sub>2</sub>/C nanocomposite. The glassy carbon electrode was polished with a 0.3  $\mu$ m followed by a 0.05  $\mu$ m alumina suspension to give a mirror finish. The MnO<sub>2</sub>/C nanocomposites were ground in an agate mortar prior to testing. 2.0 mg of MnO<sub>2</sub>/C was suspended by sonication in 1 mL of ethanol. 15  $\mu$ L of MnO<sub>2</sub>/C suspension was deposited onto the glassy carbon substrate and dried at room temperature. Electrochemical tests were performed in 1 M Na<sub>2</sub>SO<sub>4</sub> at room temperature and neutral pH between 0.4 to -0.4 V vs. Hg/Hg<sub>2</sub>SO<sub>4</sub>. Aqueous potentials cited in this article are vs. Hg/Hg<sub>2</sub>SO<sub>4</sub>. Electrochemical impedance spectroscopy measurements were made using an Autolab PGSTAT30 potentiostat. The potential was fixed at 0 V vs. Hg/Hg<sub>2</sub>SO<sub>4</sub>, and frequencies from 10 kHz to 10 mHz were analyzed.

### 5.3 RESULTS

Figure 5.1 shows the structure of the mesoporous carbon and MnO<sub>2</sub>/C nanocomposites from high resolution SEM. Small disordered mesopores are visible for all of the samples. Oxidation shows little visible change from the GMC (Fig. 5.1a) to the OGMC (Fig. 5.1b). At the lowest loading of 5.4 wt% MnO<sub>2</sub> (Fig. 5.1c), small platelet-like deposits of MnO<sub>2</sub> appear on the exterior of the carbon structure. At an intermediate loading of 16 wt% (Fig. 5.1d), these platelet-like deposits are more pronounced limiting the visibility of the pore openings. At the highest loading of 35 wt% (Fig. 5.1e), larger MnO<sub>2</sub> deposits occupy the exterior, some of which may potentially block the pores of the OGMC. Although these deposits are visible on the exterior of the particle, the majority of the MnO<sub>2</sub> may be expected reside in the interior of the OGMC since the ratio of internal surface area to external surface area is very large (10<sup>4</sup>:1).

Nitrogen porosimetry was used to characterize the BET surface area, pore volume, and pore size for the MnO<sub>2</sub>/C nanocomposites (Table 5.1, Figure 5.2). The sorption isotherms are offered in Appendix C (Fig. C.1). GMC had a surface area of 262 m<sup>2</sup>/g and a pore volume of 0.4 cm<sup>3</sup>/g. Upon oxidation, these values increase significantly to 434 m<sup>2</sup>/g and 0.54 cm<sup>3</sup>/g as the surface roughness increased.<sup>25</sup> These increases may be attributed primarily to micropores, since the GMC has almost no micropores (based on t-plot method).<sup>29</sup> At the highest loading of 35 wt% MnO<sub>2</sub>, the surface area and porosity dropped substantially to 67 m<sup>2</sup>/g and 0.09 cm<sup>3</sup>/g. The higher molecular weight of MnO<sub>2</sub> versus carbon further contributes to the decrease in specific surface area. The MnO<sub>2</sub> occupies the majority of the micropores as well as coating the mesopores of the OGMC. The average pore size changes little with the oxidation of the carbon going from 7.6 nm for the GMC to 7.5 nm for the OGMC (Fig. 5.2). At 35 wt% MnO<sub>2</sub>, the average pore size decreases to 6.7 nm with a reduction in pore volume over a wide range of pore sizes. The thickness of a uniform MnO<sub>2</sub> film inside the mesopores is estimated to be ~0.4 nm thick from the change in the mean pore diameter. From mass basis calculations assuming straight cylindrical pores, the coating thickness in an annulus would be ~0.4 nm, which

Figure 5.1: SEM images of (a) GMC, (b) OGMC, (c) 5.4 wt% MnO<sub>2</sub>/C, (d) 15 wt% MnO<sub>2</sub>/C, (e) 35 wt% MnO<sub>2</sub>/C.

Table 5.1: Capacitance (2 mV/s) and morphology of graphitic mesoporous carbon (GMC), oxidized GMC (OGMC) and composites of OGMC and MnO<sub>2</sub>

	Nitrogen sorption data			Capacitance		
	BET surface area (m <sup>2</sup> /g)	Pore volume (cm <sup>3</sup> /g)	Mean pore diameter (nm)	Gravimetric (F/g)	Areal (μF/cm <sup>2</sup> )	Volumetric (F/cm <sup>3</sup> )
GMC	262	0.40	7.6	21	7.9	24
OGMC	434	0.54	7.5	33	7.7	34
15 wt% MnO <sub>2</sub> /C	280	0.34	7.2	86	31	120
35 wt% MnO <sub>2</sub> /C	67	0.09	6.7	160	240	400

agrees remarkable well with the nitrogen sorption data. This small dimension would correspond to ~one atomic layer of  $\text{MnO}_2$ . However, from XRD and HRTEM, individual nanodomains are present with a size of ~4 nm, which is at least a few atomic layers thick, with uncoated regions between the domains.

X-ray diffraction of the nanocomposites and carbon support are shown in Figure 5.3. For the GMC, a sharp peak at  $26^\circ$  and small peak at  $42.2^\circ$ , corresponding to the (002) and (100) planes, indicate a high degree of graphitization resulting from the heat treatment at  $2600^\circ\text{C}$ . After oxidation with nitric acid, these peaks are still present. Although the  $42.2^\circ$  peak disappears at loadings greater than 20 wt%  $\text{MnO}_2$ , the sharp peak at  $26^\circ$  remains for all of the  $\text{MnO}_2/\text{C}$  nanocomposites, indicating high graphitization, and consequently high electronic conductivity. For all the samples except for 35 wt%, no peaks for  $\text{MnO}_2$  are evident indicating an amorphous layer is deposited inside of the carbon. The  $\text{MnO}_2$  is amorphous because of the small domain sizes and since the annealing temperature for the nanocomposites is only  $100^\circ\text{C}$  and not high enough to promote crystallization. However, for the highest loaded sample at 35 wt%,  $\text{MnO}_2$  peaks begin to form at  $36.8^\circ$  and  $65.7^\circ$  indicating some crystallization. These peaks correspond to the (006) and (119) crystal planes of birnessite (JCPDF#18-0802), a polymorph of  $\text{MnO}_2$ .<sup>30, 31</sup> The crystallite size is estimated to be 4.2 nm from Scherrer's equation. The crystallization at 35 wt% occurs presumably from the longer reaction time during the synthesis of the nanocomposite and the larger nanodomains. The small size of the peaks for birnessite at 35 wt% suggests that amorphous domains of  $\text{MnO}_2$  are prevalent.

From HRTEM, the graphitic structure of the GMC and OGMC are characterized by bent layered ribbon like planes representing graphene sheets (Fig. 5.4a and 5.4b). These results support the XRD observation of minimal loss in graphitization upon nitric acid treatment. At 15 wt%  $\text{MnO}_2$ , the graphene layers are visible; however, no discernable structure is evident for  $\text{MnO}_2$  (Fig. 5.4c). Here  $\text{MnO}_2$  is amorphous as given by XRD and HRTEM. At 35 wt%  $\text{MnO}_2$ , large dark spots are observable indicating  $\text{MnO}_2$  domains dispersed throughout the carbon support (Fig. 5.4d). At higher

Figure 5.3: XRD patterns for GMC, OGMC, and MnO<sub>2</sub>/C nanocomposites (spectra offset for clarity).

Figure 5.4: HRTEM images of (a) GMC, (b) OGMC, (c) 15 wt% MnO<sub>2</sub>/C, and (d), (e) 35 wt% MnO<sub>2</sub>/C.

magnification overlapping crystalline lattice planes of the MnO<sub>2</sub> polymorph birnessite are visible along with the graphene layers underneath (Fig. 5.4e). The MnO<sub>2</sub> lattice spacing is measured to be  $\sim 2.5$  Å in the (006) plane, corresponding well with the XRD (006) plane dimension of 2.44 Å for birnessite (JCPDF#18-0802). This spacing is sufficient for facile transport of Na<sup>+</sup> (0.95 Å)<sup>32</sup> throughout the birnessite lattice. The average crystallite size is estimated to be 3.8 nm, which matches well with the XRD size of 4.2 nm. Thus, HRTEM confirms the XRD result that the graphitic structure in GMC remains in the nanocomposites and the MnO<sub>2</sub> domains are on the order of  $\sim 1$  nm thickness, presumably a few atomic layers thick.

In addition to HRTEM, the nanocomposites were viewed using STEM and analyzed with EDX (Fig. 5.5). In the STEM mode, Mn with a higher atomic number than C produces a higher intensity. Fig. 5.5a and 5.5b shows the STEM images for the 15 wt% and 35 wt% MnO<sub>2</sub> samples, respectively. The images are both uniformly bright denoting the MnO<sub>2</sub> is dispersed throughout the carbon support. The 35 wt% MnO<sub>2</sub> composite appears brighter in the center where the particle is the thickest than at the edges. To further characterize the dispersion of the MnO<sub>2</sub> within the carbon, EDX analysis was performed on 15 wt% (Fig. 5.5c-e) and 35 wt% (Fig. 5.5f-h) samples. In Fig. 5.5c-h, the K-line energies for Mn, O, and C are represented in red, green, and blue, respectively. The Mn and O intensities correspond well with each other and denote MnO<sub>2</sub>. In these areas of high Mn and O intensity, the C intensity is less. For both the 15 wt% and 35 wt% EDX data, the MnO<sub>2</sub> is shown to be uniformly dispersed throughout the carbon support.

Cyclic voltammetry was carried out in 1 M Na<sub>2</sub>SO<sub>4</sub> to determine the gravimetric capacitance of the nanocomposites. The shape of the cyclic voltammograms in Fig. 5.6 is characteristic of electric double layer capacitors and MnO<sub>2</sub> redox pseudocapacitors. Relatively flat rectangular-shaped profiles are evident in the scans at 2, 20 and 200 mV/s at all MnO<sub>2</sub> contents even up to 35 wt%. At higher scan rates, the slope of the profiles can increase significantly presumably due to hindered ion and electron transport;<sup>23</sup> however, all of the composites in Fig. 5.6 exhibit high double layer charging profiles with minimal sloping character. The higher scan rates lead accordingly to higher currents as

Figure 5.5: STEM images and EDX of (a), (c) Mn, (d) O, (e) C for 15 wt% MnO<sub>2</sub>/C and (b), (f) Mn, (g) O, (h) C for 35 wt% MnO<sub>2</sub>/C.

Figure 5.6: Cyclic voltammetry curves in 1 M Na<sub>2</sub>SO<sub>4</sub> at scan rates of (a) 2 mV/s, (b) 20 mV/s, and (c) 200 mV/s

the current should scale linearly with scan rate.

Total gravimetric capacitance  $C_g$  values were calculated with the following equation

$$C_g = (\Delta I/2)/(vm) \quad (5.1)$$

where  $\Delta I$  is the current difference at 0 V in the two different scanning directions,  $v$  is the scan rate, and  $m$  is the mass of active material. The  $C_g$  as a function of scan rate is shown in Fig. 5.7a. The  $C_g$  of GMC was 21 F/g at 2 mV/s and dropped only a small amount at 200 mV/s. After oxidation of the carbon, the  $C_g$  for OGMC increased to 33 F/g at 2 mV/s as the surface area increased. The  $C_g$  fade for the OGMC was ~14% at 200 mV/s, indicating any loss in electronic conductivity from oxidation had a minor effect. As  $MnO_2$  was deposited into the carbon, the  $C_g$  increased reaching 160 F/g at 2 mV/s at 35 wt%, and 127 F/g at 200 mV/s, an eightfold improvement in  $C_g$  compared to the GMC. For the various  $MnO_2/C$  nanocomposites and pure carbon supports, the  $C_g$  drops by ~10% as the scan rate goes from 2 to 10 mV/s and then only drops by an additional ~10% from 10 to 200 mV/s.

The gravimetric  $MnO_2$  pseudocapacitance contribution is shown in Fig. 5.7b as a function of scan rate. A maximum  $C_{MnO_2}$  of 500 F/g $_{MnO_2}$  is achieved at 2 mV/s for 8.8 wt%  $MnO_2$ . At 200 mV/s for 8.8 wt%  $MnO_2$ , the  $C_{MnO_2}$  drops to only 400 F/g $_{MnO_2}$ . For all the other  $MnO_2/C$  nanocomposites, the  $C_{MnO_2}$  is 400-450 F/g $_{MnO_2}$  at 2 mV/s and drops to 310-340 F/g $_{MnO_2}$  at 200 mV/s. These  $C_{MnO_2}$  values are exceptionally large for the high scan rate of 200 mV/s. Similar to the  $C_g$ , the  $C_{MnO_2}$  drops by ~10% from 2 to 10 mV/s and by ~10% from 10 to 200 mV/s for each composite.

The maximum energy density ( $E_{max}$ ) of the  $MnO_2/C$  nanocomposites can be computed from the  $C_g$  values using the equation

$$E_{max} = \frac{1}{2}C_{cell}V^2 \quad (5.2)$$

where  $V$  is the potential window and taken to be a maximum of 1.2 V, the breakdown of water, and  $C_{cell}$  is the device capacitance ( $C_g/2$ ). The GMC has a low energy density of only 2.1 Wh/kg. With the 35 wt% sample, the energy density increases eight-fold to 16 Wh/kg at 2 mV/s. At the highest scan rate of 200 mV/s, the energy density is still 12.7

Figure 5.7: Gravimetric capacitance in 1 M Na<sub>2</sub>SO<sub>4</sub> based on (a) total mass and (b) MnO<sub>2</sub> mass as a function of scan rate.

Wh/kg. This high energy density begins to approach the values observed for batteries (>10 Wh/kg).<sup>7, 12</sup>

The areal and volumetric capacitances of the samples at 2 mV/s were calculated given the nitrogen sorption data (Table 5.1). For the GMC the areal and volumetric capacitance are 7.9  $\mu\text{F}/\text{cm}^2$  and 24  $\text{F}/\text{cm}^3$ . Upon oxidation the areal capacity drops marginally to 7.7  $\mu\text{F}/\text{cm}^2$ , but the volumetric capacitance increases to 34  $\text{F}/\text{cm}^3$ , which can be related to the increase in pore volume. Incorporation of  $\text{MnO}_2$  at 15 wt% increases the areal capacity by fourfold to 31  $\mu\text{F}/\text{cm}^2$  and the volumetric capacitance by five-fold to 120  $\text{F}/\text{cm}^3$ . With the 35 wt%  $\text{MnO}_2$ , the areal and volumetric capacitances increase dramatically to 240  $\mu\text{F}/\text{cm}^2$  and 400  $\text{F}/\text{cm}^3$ , respectively. These high values result from the low BET surface area and pore volume for the composite at the high loading.

Electrochemical impedance spectroscopy was used to characterize the resistance, response time, and diffusion coefficient of the  $\text{MnO}_2/\text{C}$  nanocomposites. Nyquist plots are shown in Fig. 5.8, which are multiplied by 0.196  $\text{cm}^2$  to normalize with respect to geometric area. The linear slopes indicate that the carbon supports and  $\text{MnO}_2/\text{C}$  nanocomposites exhibit almost purely capacitive behavior at low frequencies (high  $Z'$ ) with a phase angle of  $\sim 88^\circ$ . The Warburg impedance, in the mid-range frequency region is influenced by ion diffusion through the pores of the carbon support.<sup>33</sup> At high frequencies, capacitance is negligible, and resistance is dominant. The resistance can be manifested as a semi-circle or arc; however, these shapes were not present (Fig. 5.8). Thus, the contact resistance between  $\text{MnO}_2/\text{C}$  particles, and the particle-electrode surface were minimal.<sup>1, 34, 35</sup>

The bulk solution resistance ( $R_\Omega$ ), charge transfer resistance ( $R_{\text{ct}}$ ), and diffusional resistance in the pores ( $R_d$ ) can be extracted from the EIS data. The bulk solution resistance can be found from the real impedance x-intercept of the Nyquist plot at high frequencies.<sup>33, 36</sup> For all of the samples, the bulk solution resistance is  $\sim 2 \Omega \text{ cm}^2$ . This bulk solution resistance is large with the beaker cell configuration used and would be lower for a two electrode setup with a thin electrolyte layer.<sup>19</sup> The charge transfer resistance can be found from a plot of  $Z'$  vs.  $1/\omega^{1/2}$  where  $\omega$  is the angular frequency and

Figure 5.8: Nyquist plots for GMC, OGMC, 15 wt%, and 35 wt% MnO<sub>2</sub>/C nanocomposites given with respect to geometric area.

the y-intercept gives  $R_{ct} + R_{\Omega}$ .<sup>33</sup> For all the samples, the  $R_{ct}$  is  $<0.2 \Omega \text{ cm}^2$  indicating charge transfer in the thin  $\text{MnO}_2$  domains adds little to the resistance. The  $R_d$ , which describes the diffusion of ions in the porous structure, is found from extrapolating the Warburg impedance ( $R_d + R_{\Omega}$ ) at the knee frequency, which is intersection of the Warburg and capacitive branch in the Nyquist plot, to the real impedance axis.<sup>21, 36</sup> Upon subtracting  $R_{\Omega}$  from the Warburg impedance, the  $R_d$  is given in Table 5.2. For the GMC,  $R_d$  is very small at  $0.20 \Omega \text{ cm}^2$ . For the OGMC,  $R_d$  increases by almost 2 orders of magnitude to  $23 \Omega \text{ cm}^2$ . With 15 wt% and 35 wt%  $\text{MnO}_2$ ,  $R_d$  drops back down to  $0.80 \Omega \text{ cm}^2$  and  $1.2 \Omega \text{ cm}^2$ , respectively. The large increase in  $R_d$  for the OGMC possibly results from the nitric acid treatment introducing surface functionalities and from poor ion transport through the micropores.<sup>13</sup> The larger  $R_d$  for the  $\text{MnO}_2/\text{C}$  nanocomposites compared to GMC results from the narrowing pore size distribution.

The real part of the capacitance can be calculated from the Nyquist plots using the imaginary part of the impedance,  $Z''$ . The real part of the total gravimetric capacitance,  $C_g'$ , is given by the equation<sup>37-39</sup>

$$C_g' = 1/(\omega(-Z''(\omega))m) \quad (5.3).$$

The Bode plot is shown in Fig. 5.9. For GMC,  $C_g'$  fade with frequency is minimal. With oxidation of the carbon, the higher surface area results in an increased capacitance at low frequencies. However at higher frequencies, the  $C_g'$  for OGMC drops below that of the GMC, as a result of the much higher diffusional resistance. With  $\text{MnO}_2$  incorporated into carbon support, the increase in the  $C_g'$  at low frequencies is similar to that seen from cyclic voltammetry. The  $C_g'$  decreases for the  $\text{MnO}_2/\text{C}$  nanocomposites at  $>1 \text{ Hz}$  and converges with the GMC and OGMC  $C_g'$  at the highest frequencies. At the highest frequencies, the Faradaic redox process from  $\text{MnO}_2$  becomes too slow to contribute to the  $C_g'$ .

The dielectric relaxation time constant,  $\tau$ , of the carbon support and  $\text{MnO}_2/\text{C}$  nanocomposites was computed from the Bode plot of the imaginary capacitance,  $C_g''$  (Fig. 5.10). The  $C_g''$  is given by<sup>21, 37, 38</sup>

$$C_g'' = Z'(\omega)/(\omega|Z(\omega)|^2m) \quad (5.4).$$

Table 5.2: Parameters extracted from electrochemical impedance spectroscopy.

Sample	Diffusional resistance ( $\Omega \text{ cm}^2$ )	Time constant (s)	Diffusion coefficient ( $\text{cm}^2/\text{s}$ )
GMC	0.20	0.02	$2.1 \times 10^{-7}$
OGMC	23	1.0	$2.1 \times 10^{-8}$
15 wt% $\text{MnO}_2/\text{C}$	0.80	0.25	$2.9 \times 10^{-8}$
35 wt% $\text{MnO}_2/\text{C}$	1.2	0.40	$4.3 \times 10^{-9}$

Figure 5.9: Bode plot from the real part of capacitance using EIS data for GMC, OGMC, 15 wt% MnO<sub>2</sub>/C and 35 wt% MnO<sub>2</sub>/C nanocomposites.

Figure 5.10: Bode plot for the imaginary part of the capacitance to determine dielectric relaxation time constants for GMC, OGMC, 15 wt% MnO<sub>2</sub>/C, and 35 wt% MnO<sub>2</sub>/C.

The frequency at the maxima of the Bode plot is the inverse of  $\tau$  (Table 5.2). This  $\tau$  provides a measure for the speed at which the electrode can discharge (i.e. power density).<sup>21</sup> For GMC,  $\tau$  is only 0.02 s. With oxidation, it increases to 1.0 s for OGMC, but is only 0.4 s at 35 wt% MnO<sub>2</sub>. The  $\tau$  follow the same trend as for the diffusional resistances with a large  $\tau$  for OGMC possibly resulting from micropores.<sup>13</sup> Using  $\tau$  and estimating the diffusion length,  $L$ , as the thickness of the electrode film, the diffusion coefficient  $D$  of Na<sup>+</sup> (Table 5.2) can be calculated from  $D = L^2/\tau$ . The  $D$  is high at  $2.1 \times 10^{-7}$  cm<sup>2</sup>/s for GMC, and decreases about an order of magnitude for OGMC. At 35% MnO<sub>2</sub>, the  $D$  of  $4.3 \times 10^{-8}$  cm<sup>2</sup>/s is still quite high. With MnO<sub>2</sub> added to the porous carbon support, the  $D$  decreases slightly since ions must diffuse through the solid MnO<sub>2</sub> layer for redox.

## 5.4 DISCUSSION

A key advancement of this study over the previous chapter with a 3D mesoporous nanocomposite was the large improvement in the electronic conductivity of the carbon support as a result of the soft-template technique and high heat treatment temperature. Previous studies with MnO<sub>x</sub>/carbon composites have utilized primarily hard-templated mesoporous carbon (HMC) supports synthesized using mesoporous silica SBA-15.<sup>22, 23</sup> Fuertes et al. have reported the electronic conductivity for HMC increases by tenfold with an increase of heat treatment temperature from 900 °C (0.30 S/cm) to 2300 °C (4.2 S/cm).<sup>16</sup> Because of the thin carbon filaments of the pore-walls of hard-templated carbons, pore collapse upon graphitization at high temperatures can increase the electronic conductivity only moderately.<sup>24</sup> For HMC supports used for MnO<sub>x</sub>/carbon composites that were heat treated at ~900 °C, a low degree of graphitic character was observed via broad XRD peaks for carbon,<sup>22, 23</sup> resulting in an estimated electronic conductivity of ~0.3 S/cm.<sup>16</sup> The GMC support in the current study was synthesized via a soft-template strategy.<sup>26-28</sup> At a low heat treatment temperature (~900 °C), carbons produced by hard- and soft-templates have similar electronic conductivities. However, at

high heat treatment temperatures ( $>2300\text{ }^{\circ}\text{C}$ ), the electronic conductivity of  $330\text{ S/cm}$ <sup>24</sup> for soft-templated carbons is  $\sim 100$ -fold higher than for hard-templated carbons. The soft-template route leads to stronger pore-wall structures through covalently/hydrogen bonded frameworks and thick pore-walls.<sup>24, 27</sup> The soft-template technique allows for more facile graphitization of the carbon to give higher electronic conductivities at high heat treatment temperatures.

The  $\text{MnO}_2/\text{C}$  nanocomposites were synthesized via a self-limiting redox reaction between the OGMC and potassium permanganate. The carbon support serves as a sacrificial reducing agent for heterogeneous nucleation of  $\text{MnO}_2$  on the carbon surface.<sup>40</sup> By varying the reaction time and permanganate to carbon ratio, the  $\text{MnO}_2$  loading can be controlled. In neutral pH, the permanganate ions diffuse readily throughout the porous carbon support to form a relatively uniform dispersion of  $\text{MnO}_2$  nanodomains.<sup>20, 21</sup> For the as-synthesized GMC, the loadings were  $<1\text{ wt}\%$   $\text{MnO}_2$  as the surface hydrophobicity impeded the aqueous precursor from fully penetrating the pores and wetting the carbon surface. In contrast, loadings of  $30\text{ wt}\%$   $\text{MnO}_2$  were achieved readily for more wettable hydrophilic amorphous carbons with less graphitic content and more polar oxygenated sites (Chapter 4). In order to facilitate the deposition of  $\text{MnO}_2$  onto the hydrophobic GMC carbon, it was first oxidized in nitric acid.<sup>41</sup> The nitric acid dissolved very little of the graphitic carbon while only slightly increasing the surface area, as shown in Table 5.1, consistent with previous studies.<sup>25, 41</sup> Oxidation of the carbon increases the oxygen content (e.g. polar acidic groups) at edge plane sites<sup>2</sup> which aids wetting by the aqueous  $\text{MnO}_2$  precursor, resulting in high loadings. Loadings as high as  $35\text{ wt}\%$  in  $0.1\text{ M}$   $\text{KMnO}_4$  were achieved on OGMC upon deposition for 24 hours.

The  $\text{MnO}_2$  charge storage mechanism occurs via insertion/extraction sodium ions and/or possibly protons via

where  $\text{X}^+ = \text{Na}^+$  or  $\text{H}^+$ . The reaction is sufficiently fast to give a high power density.<sup>3</sup> The relative pseudocapacitive contributions from surface and intercalation capacitance can be estimated from the scan rate dependence with plots of  $C_{\text{MnO}_2}$  vs.  $v^{-1/2}$  and  $(C_{\text{MnO}_2})^{-1}$  vs.  $v^{1/2}$ , which both show linear behavior (Appendix C, Fig. C.2).<sup>42, 43</sup> At high scan rates,

ion diffusion is limited and only surface capacitance contributes, whereas at low scan rates, both surface and intercalation capacitance are present. The surface capacitance can be found from extrapolation of  $C_{\text{MnO}_2}$  to  $v=\infty$  (i.e.  $v^{-1/2}=0$ ), and the total pseudocapacitance can be extrapolated from  $v=0$  (i.e.  $v^{1/2}=0$ ). The ratio of the surface contribution to the total pseudocapacitance is found to be high at 81-88% for all of the composites, which is consistent with the linear dependence between current and  $v$  (Appendix C, Fig. C.3a). The high surface contribution describes the more rapid surface pseudocapacitance, relative to the slower intercalation based charge storage mechanism which is diffusional in nature and would exhibit a linear dependence between current and  $v^{1/2}$ , which is not the case for the composites (Appendix C, Fig. C.3b).<sup>44</sup> The high contribution of surface capacitance is consistent with a recent study of 2-3 nm thick  $\text{RuO}_2$  nanoskins.<sup>45</sup> Hence, the high surface pseudocapacitance is given by the high fraction of the Mn atoms on the surface for the extremely small nanodomains ( $\sim 1$  nm) based on nitrogen porosimetry, XRD, and HRTEM characterization.

The effect of the electronic conductivity of the carbon support on  $C_{\text{MnO}_2}$  may be examined by comparing the results for OGMC with the previous chapter on amorphous mesoporous carbon (AMC), with essentially the same disordered pore structure and  $\text{MnO}_2$  loading. The  $C_{\text{MnO}_2}$  was similar ( $\sim 500$  F/g $_{\text{MnO}_2}$ ) for AMC and OGMC loaded samples at low loadings and low scan rates (Table 5.3) where the  $\text{MnO}_2$  nanodomains are very small. However, with higher loadings and at higher scan rates, the  $C_{\text{MnO}_2}$  is over twofold greater for OGMC supported  $\text{MnO}_2$ . In the previous chapter, the AMC was graphitized at 850 °C giving a conductivity of only 0.25 S/cm,<sup>24</sup> and the  $C_{\text{MnO}_2}$  fade was >30% going from 2 to 100 mV/s. The  $\text{Na}^+$  diffusion coefficient was  $4.7 \times 10^{-10}$  cm<sup>2</sup>/s for 30 wt%  $\text{MnO}_2$ /AMC, as determined from chronoamperometry. Considering the limit or boundary condition where all of the resistance is in the diffusion through  $\text{MnO}_2$ , for a short time of 0.01 s, the diffusion length would be 22 nm, well above the  $\sim 4$  nm  $\text{MnO}_2$  domains observed in the AMC support. Thus, other resistances were present, in particular, the low electronic conductivity of the carbon support. With GMC, a much more conductive carbon support, the  $C_{\text{MnO}_2}$  fade is only  $\sim 20\%$  going from 2 to 100 mV/s (Table 5.3). With a  $\text{Na}^+$  diffusion coefficient of  $4.3 \times 10^{-9}$  cm<sup>2</sup>/s for 35 wt%  $\text{MnO}_2$ , the

Table 5.3: Comparison of MnO<sub>2</sub> gravimetric capacitance for MnO<sub>2</sub> modified disordered mesoporous carbon supports in 1 M Na<sub>2</sub>SO<sub>4</sub>. Amorphous carbon data taken from Chapter 4.

MnO <sub>2</sub> /Carbon Composite	C <sub>g</sub> , MnO <sub>2</sub> mass (F/g <sub>MnO2</sub> )	
	2 mV/s	100 mV/s
8.4 wt% / Amorphous	507	188
30 wt% / Amorphous	199	137
8.8 wt% / Graphitic	500	413
35 wt% / Graphitic	393	315

diffusion length in  $\text{MnO}_2$  would be 66 nm ( $\tau = 0.01$  s), far above the  $\sim 4$  nm  $\text{MnO}_2$  domains. Here, the diffusion coefficient is an order of magnitude larger than for the  $\text{MnO}_2/\text{AMC}$  composite. For both the previous AMC and current OGMC nanocomposites, the diffusion coefficient decreases with increased  $\text{MnO}_2$  loading, falling by an order of magnitude at the highest  $\text{MnO}_2$  loading relative to the pure carbon support. This decrease is caused by a small decrease in pore size upon coating with  $\text{MnO}_2$ , and more significantly, by slower diffusion through the thicker  $\text{MnO}_2$  domains. Given the sufficiently high diffusion lengths in both amorphous and graphitized carbon supported  $\text{MnO}_2$  composites, the much higher  $C_{\text{MnO}_2}$  at high scan rates (315-413 F/g $_{\text{MnO}_2}$ ) and lower  $C_{\text{MnO}_2}$  fade with OGMC composites is influenced markedly by the higher electronic conductivity. The high performance results from the fast ion transport in the 3D disordered mesopores and thin, primarily amorphous,  $\text{MnO}_2$  nanodomains combined with the high electronic conductivity.

The values of  $C_{\text{MnO}_2}$  on highly conductive GMC are also larger than for manganese oxide nanodomains formed on an ordered amorphous mesoporous carbon support reported recently.<sup>23</sup> Ordered mesoporous carbon supports synthesized via a hard template technique with amorphous  $\text{MnO}_2$  nanoparticles embedded in the pore walls were prepared via electroless deposition with  $\text{KMnO}_4$ . Dong et al achieved a highest loading of 26 wt%  $\text{MnO}_2$  inside the 3.6 nm pores of the carbon support.<sup>23</sup> At 26 wt%  $\text{MnO}_2$ , analysis of their CV curve in 2 M KCl in the middle of the current-potential profile gives a  $C_{\text{MnO}_2}$  of 167 F/g $_{\text{MnO}_2}$  at 5 mV/s, which would drop substantially at higher rates. In the study by Dong et al.<sup>23</sup> and the previous chapter, the lower conductivity of the mesoporous carbons, graphitized at relatively low temperatures ( $\sim 900$  °C), led to lower values of  $C_{\text{MnO}_2}$  at high scan rates and greater  $C_{\text{MnO}_2}$  fade with scan rate, relative to the current study with highly conductive GMC. The current-potential curves for Dong et al. also do not exhibit flat rectangular profiles at 5 mV/s<sup>23</sup> which are seen in the current study for a high scan rate of 200 mV/s, where the C support is more conductive. Furthermore, the larger pore size ( $\sim 8$  nm) of the GMC support allows for high loadings up to 35 wt%  $\text{MnO}_2$ . The large pore size and disordered pore structure of the GMC

provides for more facile electrolyte mass transport throughout the porous support than for mesoporous carbons containing small pore sizes<sup>13</sup> and ordered structure.<sup>7, 46</sup>

3D disordered carbon nanofoams (pore size distribution 1-100 nm) have been used as carbon supports for electroless deposition of MnO<sub>2</sub> particles of size 10-30 nm.<sup>20, 21, 47</sup> A high C<sub>g</sub> in 1 M Na<sub>2</sub>SO<sub>4</sub> of 130 F/g at 2 mV/s was achieved at 37 wt% MnO<sub>2</sub> with a C<sub>MnO<sub>2</sub></sub> of ~300 F/g<sub>MnO<sub>2</sub></sub>. The dielectric relaxation time constant,  $\tau$ , for the bare carbon nanofoam was 7.1 s and increased to 80 s with 37 wt% MnO<sub>2</sub>. In the current study,  $\tau$  was much lower at 0.02 s for the GMC and 0.40 s with 35 wt% MnO<sub>2</sub>/C. The larger  $\tau$  for the carbon nanofoam results in part from the lower heat treatment temperature (1000 °C)<sup>21</sup>, and consequently, moderately lower electronic conductivity (25-100 S/cm, Marketech, Inc.) compared to the GMC (330 S/cm).<sup>24</sup> From the Bode plots, the drop-off in C<sub>g</sub> for the 37 wt% MnO<sub>2</sub>/nanofoam is at ~0.02 Hz<sup>21</sup> compared to the higher frequency of ~1 Hz for 35 wt% MnO<sub>2</sub>/C in the current study. The higher drop-off frequency is due in part to the higher electronic conductivity. The diffusional resistance for the 37 wt% MnO<sub>2</sub>/nanofoam (0.46  $\Omega$  cm<sup>2</sup>)<sup>21</sup> is lower than for the 35 wt% MnO<sub>2</sub>/C (1.2  $\Omega$  cm<sup>2</sup>) in the current study. The slightly lower diffusional resistance for the nanofoam composite possibly results from the larger macropores present which would aid electrolyte mass transport. The carbon nanofoam supported MnO<sub>2</sub> is a good alternative; however, the higher electronic conductivity and small MnO<sub>2</sub> domain sizes in the present study with GMC supported MnO<sub>2</sub> lead to higher C<sub>MnO<sub>2</sub></sub> at high rates.

Carbonaceous materials such as carbon nanotubes possess high electronic conductivities which are desirable for EDLCs. For instance, CNTs can have conductivities as high as 1000 S/cm, depending on their preparation.<sup>14</sup> Mesoporous carbons have reported electronic conductivities upwards of 330 S/cm<sup>24</sup> as with the GMC support in the current study. As such, designer mesoporous supports offer the benefit of pore walls composed of sp<sup>2</sup> hybridized graphite for high electronic conductivity, as well as tailored pore size, and 3D pore structure. Possibly with further optimization in electronic conductivity and porosity of the carbon support the specific capacitance of MnO<sub>2</sub> can approach the theoretical value of 1370 F/g<sub>MnO<sub>2</sub></sub>.<sup>10</sup>

## 5.5 CONCLUSIONS

Herein, we have demonstrated high gravimetric pseudocapacitance of ~1 nm thick  $\text{MnO}_2$  domains well dispersed in a highly graphitic 3D disordered mesoporous carbon support with high electronic conductivity. Despite the high loading of 35 wt%  $\text{MnO}_2$ , the  $C_{\text{MnO}_2}$  of 310 F/g $_{\text{MnO}_2}$  was over twofold larger than amorphous carbon supported  $\text{MnO}_2$  at a high scan rate of 200 mV/s. Oxidation of the carbon surface at edge plane sites enabled wetting to achieve deposition of the  $\text{MnO}_2$  at high loadings. The soft-template synthesis technique and high heat treatment temperature of 2600 °C promoted a high degree of graphitization for the carbon support to yield a high electronic conductivity (330 S/cm).<sup>24</sup> Mesoporous supports offer the benefit of highly conductive pore walls composed of  $\text{sp}^2$  hybridized graphite domains with high surface area interconnected 3D mesopores. The ~8 nm disordered pores provide sufficient space for thin  $\text{MnO}_2$  domains at high loadings along with ion diffusion via multiple flow pathways.<sup>46</sup> The thin  $\text{MnO}_2$  nanodomains produce a high  $C_{\text{MnO}_2}$  primarily via a surface redox reaction mechanism at high rates. With rapid electron and ion transfer to the small  $\text{MnO}_2$  domains, high  $C_{\text{MnO}_2}$  values are achieved at high rates of 200 mV/s.

## Chapter 6

### Conclusions and Recommendations

#### 6.1 CONCLUSIONS

##### 6.1.1 Charging Mechanism of Carbon Black Particles in Low-Permittivity Media

Electrophoretic mobilities of highly absorbing carbon black particles in concentrated dispersions at 1 wt% were measured using differential-phase optical coherence tomography (DP-OCT) with sufficient spectrogram intensities for facile analysis. An advantage of the narrow electrode spacing (0.18 mm) in DP-OCT is that higher strength electric fields, needed to measure the small mobilities in the low-permittivity solvent accurately, may be realized at lower absolute potentials. Zeta potentials in the range of -24 mV to -12 mV were measured for surfactant concentrations from 1 mM to 100 mM AOT-toluene. The electrostatic charging mechanism of the carbon black particles depends on the preferential partitioning of sodium cations between the hydrated reverse micelles in the double-layer and the adsorbed surfactant on the particle surface. At low concentrations the cations prefer the larger, more hydrated reverse micelles resulting in more negative zeta potentials, whereas at high concentrations the cations partition towards the increasingly hydrated surfactant-laden particle surface and lower the magnitude of the particle charge.

##### 6.1.2 Electrophoretic Deposition of Au Nanocrystals inside a Mesoporous TiO<sub>2</sub> Film

Small charged Au nanocrystals of ~3.1 nm in a low-permittivity solvent were electrophoretically deposited into ordered mesoporous TiO<sub>2</sub> films on ITO/glass electrodes, with loadings up to 21 wt%. The loadings were not limited kinetically in 10 min relative to 20 h, indicating that the open geometry of the mesochannels is beneficial for diffusion of the nanocrystals. The Au nanocrystals are highly dispersed throughout

the mesopores with only a small fraction ( $\sim 0.3$  wt%) occupying the top planar surface of the film. The relatively small potential drop ( $\sim 0.05$  V) across the non-conducting film is beneficial for electrophoretic deposition of Au nanocrystals. Both variable angle spectroscopic ellipsometry measurements of the anisotropy of the imaginary refractive index,  $k$ , and XPS depth profiling studies indicated that Au nanocrystals were dispersed within the vertically aligned mesopores and distributed throughout the film. Presumably, the high coverage of the strongly-bound thiol ligands on the Au nanocrystals weakens the Au/TiO<sub>2</sub> interactions, leading to low loadings of  $<5$  wt% Au. Therefore, electrophoresis is beneficial for increasing the concentration of nanocrystals near the pore openings of the film, enhancing the thermodynamic driving force for adsorption of Au nanocrystals upon mesoporous TiO<sub>2</sub> with high loadings.

### **6.1.3 Hybrid MnO<sub>2</sub>/Mesoporous Carbon Composites for Redox Pseudocapacitors**

Composites formed by electroless deposition of redox-active MnO<sub>2</sub> nanoparticles in disordered mesoporous carbon were tested as electrochemical capacitors. The MnO<sub>2</sub> pseudocapacitance augmented the electric double-layer capacitance of the carbon support to give a high gravimetric capacitance composite. Enhancements of threefold and eightfold in gravimetric capacitance were achieved with amorphous (AMC) and graphitic (GMC) carbon supports, respectively, at high loadings of MnO<sub>2</sub>. A high loading of 30 wt% MnO<sub>2</sub> was achieved in the AMC, whereas oxidation of the GMC was required to achieve a loading of 35 wt% MnO<sub>2</sub>. Hence, the wettability of the aqueous MnO<sub>2</sub> precursor on the carbon support is crucial in attaining high loadings of MnO<sub>2</sub>. AMC, which contains more oxygen functional groups, is easily wet inside the pores, whereas GMC must be oxidized to introduce these oxygen functionalities for deposition of MnO<sub>2</sub>. The  $\sim 8$  nm pores of the carbon supports allow for enough space for  $\sim 1$  nm thick MnO<sub>2</sub> domains to be formed throughout the support while still preserving open mesopores to facilitate ion transport. High MnO<sub>2</sub> pseudocapacitances of  $>500$  F/g<sub>MnO<sub>2</sub></sub> were measured at low loadings ( $<10$  wt%) and low scan rate of 2 mV/s for both supports. At these conditions, both electrons and ions have sufficient time to move through the carbon

support and pores for redox of the  $\text{MnO}_2$  domains. However, at high loadings of  $\geq 30$  wt%  $\text{MnO}_2$  and high scan rate of  $\geq 100$  mV/s, the effects of the higher electronic conductivity of the GMC are more evident with  $\text{MnO}_2/\text{GMC}$  giving more than twofold higher  $\text{MnO}_2$  pseudocapacitance, relative to  $\text{MnO}_2/\text{AMC}$ . Heat treatment at  $2600^\circ\text{C}$  for the GMC resulted in a  $\sim 1000\times$  increase in electronic conductivity, compared to heat treatment at  $850^\circ\text{C}$  for the AMC.<sup>1</sup> Since sodium ion diffusion was facile through both supports, the higher  $\text{MnO}_2$  pseudocapacitance for  $\text{MnO}_2/\text{GMC}$  is attributed to its much higher electronic conductivity. Mesoporous supports with highly conductive pore walls composed of graphene and high surface area interconnected 3D mesopores offer the potential for synthesizing novel nanocomposites for high  $\text{MnO}_2$  pseudocapacitance. The high  $\text{MnO}_2$  pseudocapacitance of these nanodomains at high scan rates is a significant advancement towards the ultimate goal of high energy and power densities for electrochemical capacitors with thin conformal coatings of  $\text{MnO}_2$ .

## **6.2 RECOMMENDATIONS**

### **6.2.1 Electrophoretic Mobilities of Metal Nanocrystals**

Differential phase optical coherence tomography (DP-OCT) has been successfully used to measure electrophoretic mobilities of highly scattering  $\text{TiO}_2$  (Smith, 2007) and highly absorbing carbon black colloids in this dissertation. These colloids were relatively large with  $\sim 200$  nm diameters. It would be of interest to extend the domain of DP-OCT to measure 3 to 100 nm diameter nanoparticles. Many nanoparticles are synthesized in nonaqueous solvents,<sup>2</sup> which makes DP-OCT ideal for measuring the low expected mobilities. Mobilities of Au and PbSe nanocrystals dispersed in chloroform with various surfactants have been measured showing charges of one or two electronic charges per nanocrystal.<sup>3, 4</sup> Further study of charged nanocrystal dispersions would be beneficial for nanoparticle assemblies and nanocomposite formation.

### **6.2.2 Conductive Carbon Supports and Crystalline MnO<sub>2</sub> for Redox Pseudocapacitors**

Further research can be done on hybrid MnO<sub>2</sub>/carbon composites to understand the MnO<sub>2</sub> pseudocapacitance behavior to reach the theoretical value of 1370 F/g<sub>MnO<sub>2</sub></sub>.<sup>5</sup> As shown herein the electronic conductivity of the carbon support can have a large effect on the pseudocapacitance at high scan rates. Hence one route would be to find ways to further increase the electronic conductivity of the carbon support to facilitate electron transport to the MnO<sub>2</sub> domains to enhance the redox reactions. An alternative would be to change the crystallinity of the MnO<sub>2</sub> domains. Herein, the MnO<sub>2</sub> domains were primarily amorphous given the low annealing temperature of the composite. Increasing the temperature would induce crystallization of the MnO<sub>2</sub> possibly leading to more facile ion and electron diffusion through the MnO<sub>2</sub>. Presynthesis of MnO<sub>2</sub> nanocrystals followed by infusion into mesoporous carbon can also be done to control the MnO<sub>2</sub> crystallinity, morphology, and size. The electrolyte in the current study is also known to give a lower capacitance compared to other, more basic electrolytes.<sup>6</sup> Hence, switching to more a more basic electrolyte such as KOH would lead to improved ion penetration through the pores and MnO<sub>2</sub> to give higher pseudocapacitance. Varying the MnO<sub>2</sub> deposition method also would lead to different crystalline formations and the possibility to precisely form a ~1 nm thin conformal coating throughout the porous carbon support.

### **6.2.3 Mixed Metal Oxides on Mesoporous Carbon Supports for Redox Pseudocapacitors**

Other transition metal oxides show redox-active pseudocapacitive behavior similar to MnO<sub>2</sub>. These include oxides of Ru, Mo, Fe, V, Cr, W, Ir, Ni, and Co to name a few.<sup>7-10</sup> Relatively few studies have looked at combinations of these metal oxides to see the effects of cascading redox reactions for pseudocapacitors. By using mixed metal oxides, multiple oxidation states can exist, increasing the charge storage capacity. Combining these mixed metal oxides, which intrinsically could possess high electronic conductivity, with a 3D high surface area pore architecture would further enhance the energy density of these pseudocapacitive materials.

## Appendix C

### MnO<sub>2</sub>/Graphitic Mesoporous Carbon Composites for Electrochemical Capacitors

These figures relate to MnO<sub>2</sub>/graphitic mesoporous carbon (GMC) composites for electrochemical capacitors, as described in Chapter 5.

Figure C.1: Nitrogen sorption isotherms for GMC, OGMC, 15 wt% MnO<sub>2</sub>/C, and 35% MnO<sub>2</sub>/C.

Figure C.2: Linear dependence of (a)  $C_{MnO_2}$  with  $v^{-1/2}$  and (b)  $(C_{MnO_2})^{-1}$  with  $v^{1/2}$  to determine the surface contribution to pseudocapacitance compared to the total capacitance.

Figure C.3: (a) Linear dependence of current with  $v$  and (b) nonlinear behavior of current with  $v^{1/2}$  indicating that the capacitance is based on a surface mechanism and is not diffusion limited.

## Appendix D

### **MnO<sub>2</sub>/Carbon Nanocomposites using Various Carbon Supports for Electrochemical Capacitors**

This appendix contains experimental details and results for two more carbon supports used in the formation of MnO<sub>2</sub>/C composites tested for electrochemical capacitors. One support is a small pore disordered amorphous mesoporous carbon support (SMC) with a mean pore size of ~3.8 nm. The other support is an ordered amorphous mesoporous carbon support (OMC) with a mean pore size of ~7.4 nm.

#### **D.1 EXPERIMENTAL SECTION**

##### **D.1.1 Materials**

All chemicals were used as received. Sodium sulfate (>99%) was acquired from Sigma-Aldrich Cooperation, and potassium permanganate and ethanol (Absolute 200 proof) from Fisher Scientific. High purity deionized water (resistance ~18 MΩ-cm) was used. Argon (research grade, 99.999% purity) was purchased from Praxair.

##### **D.1.2 Small Pore Disordered Amorphous Mesoporous Carbon (SMC) Synthesis**

In a typical synthesis,<sup>1</sup> 1.1 g of resorcinol and 0.77 g of F87 were dissolved in 4.5 mL of EtOH and 4.5 mL of HCl aqueous solution (3.0 M). To this solution, 1.3 g of formaldehyde (37%) was then added. After stirring for about 11 min at room temperature, the clear mixture turned turbid, indicating the formation of RF-F87 nanocomposite and a phase separation. The polymer-rich gel phase was obtained by centrifugation at 9500 rpm for 4 min after the mixture was stirred for 40 min. The gel was then loaded on a large Petri dish, dried at room temperature overnight, and subsequently cured at 80 °C and 120 °C for 24 h each. Carbonization was carried out under N<sub>2</sub> atmosphere at 400 °C for 2 h with a heating rate of 1 °C/min, which was followed by further treatment at 850 °C for 3 h with a heating rate of 5 °C/min.

### **D.1.3 Ordered Mesoporous Carbon (OMC) Synthesis**

In a typical synthesis,<sup>2</sup> 1.1 g of resorcinol and 1.1 g of F127 were dissolved in 4.5 mL of EtOH and 4.5 mL of HCl aqueous solution (3.0 M). To this solution, 1.3 g of formaldehyde (37%) was then added. After stirring for about 11 min at room temperature, the clear mixture turned turbid, indicating the formation of RF-F127 nanocomposite and a phase separation. The polymer-rich gel phase was obtained by centrifugation at 9500 rpm for 4 min after the mixture was stirred for 40 min. The gel was then loaded on a large Petri dish, dried at room temperature overnight, and subsequently cured at 80 °C and 120 °C for 24 h each. Carbonization was carried out under N<sub>2</sub> atmosphere at 400 °C for 2 h with a heating rate of 1 °C/min, which was followed by further treatment at 850 °C for 3 h with a heating rate of 5 °C/min.

### **D.1.4 Preparation of MnO<sub>2</sub>/SMC Composites**

30 mg of SMC was mixed with 10 mL of aqueous KMnO<sub>4</sub> solution of known concentration ranging from 0.001 M to 0.1 M and mixed for 10 min to 24 hrs. The solution was filtered and washed with DI water to remove un-reacted KMnO<sub>4</sub>. The MnO<sub>2</sub>/SMC nanocomposite was subsequently calcined in air at 100 °C overnight.

### **D.1.5 Preparation of MnO<sub>2</sub>/OMC Composites**

30 mg of OMC was mixed with 10 mL of aqueous KMnO<sub>4</sub> solution of known concentration ranging from 0.001 M to 0.1 M and mixed for 10 min. The solution was filtered and washed with DI water to remove un-reacted KMnO<sub>4</sub>. The MnO<sub>2</sub>/OMC nanocomposite was subsequently calcined in air at 100 °C overnight.

### **D.1.7 Characterization**

Wide angle X-ray diffraction (XRD) was performed with samples prepared on a quartz slide using a Bruker-Nonius D8 Advance diffractometer. Samples were analyzed in 0.05 deg increments with a dwell time of 10 s. The average nanocrystal size was estimated from the Scherrer equation using JADE software (by Molecular Diffraction Inc).

The MnO<sub>2</sub> content was determined using energy dispersive X-ray analysis using a LEO 1530 SEM equipped with an IXRF EDX system, the latter operated with a 20 kV electron beam and 60 μm aperture (average counts ~2000 s<sup>-1</sup>).

Nitrogen sorption analysis was performed on a Micromeritics Tristar 3000 analyzer at -196 °C. Prior to measurements, the samples were heated at 150 °C with flowing N<sub>2</sub> at a Micromeritics FlowPrep 060 sample degas system for 4 h. The specific surface area was calculated using the BET method from the nitrogen adsorption data in the relative pressure range (P/P<sub>0</sub>) of 0.04-0.30.

Electrochemical measurements were carried out using a CHI 832A electrochemical analyzer (CH instruments Inc.). A three-electrode cell with a Au wire counter electrode and a Hg/Hg<sub>2</sub>SO<sub>4</sub> reference electrode were used. A glassy carbon electrode (0.196 cm<sup>2</sup>, from Pine Instruments) was used as a substrate for the nanocomposite. The glassy carbon electrode was polished with a 0.3 μm followed by a 0.05 μm alumina suspension to give a mirror finish. The MnO<sub>2</sub>/C nanocomposites were ground in an agate mortar prior to testing. 2.0 mg of MnO<sub>2</sub>/C was suspended by sonication in 1 mL of ethanol. 15 μL of MnO<sub>2</sub>/C suspension was deposited onto the glassy carbon substrate and dried at room temperature. Electrochemical tests were done in 1 M Na<sub>2</sub>SO<sub>4</sub> at room temperature.

## D.2 RESULTS

### D.2.1 MnO<sub>2</sub>/SMC composites

Figure D.1: Nitrogen sorption isotherm and pore size distribution data for SMC.

Figure D.2: XRD of SMC and 10 wt% MnO<sub>2</sub>/SMC.

Table D.1: Total gravimetric capacitance values at scan rates for SMC and MnO<sub>2</sub>/SMC nanocomposites in 1 M Na<sub>2</sub>SO<sub>4</sub>.

	Scan rate (mV/s) dependence of total gravimetric capacitance (F/g)				
MnO <sub>2</sub> content (wt%)	2	10	20	100	200
0%	51	38	33	26	24
2.2%	61	48	44	38	35
7.6%	81	67	63	55	50
10 %	87	71	64	49	42
18%	103	74	60	35	27
30%	110	74	55	28	20

Table D.2: Gravimetric MnO<sub>2</sub> pseudocapacitance values at scan rates for MnO<sub>2</sub>/SMC nanocomposites in 1 M Na<sub>2</sub>SO<sub>4</sub>.

	Scan rate (mV/s) dependence of gravimetric MnO <sub>2</sub> pseudocapacitance (F/g <sub>MnO2</sub> )				
MnO <sub>2</sub> content (wt%)	2	10	20	100	200
2.2%	537	492	520	562	551
7.6%	453	417	420	402	372
10%	416	366	337	257	212
18%	345	242	184	74	44
30%	251	159	108	31	12

### D.2.2 MnO<sub>2</sub>/OMC composites

Figure D.3: Nitrogen sorption isotherm and pore size distribution data for OMC.

Figure D.4: XRD of OMC and 10 wt% MnO<sub>2</sub>/OMC.

Table D.3: Total gravimetric capacitance values at scan rates for OMC and MnO<sub>2</sub>/OMC nanocomposites in 1 M Na<sub>2</sub>SO<sub>4</sub>.

	Scan rate (mV/s) dependence of total gravimetric capacitance (F/g)				
MnO <sub>2</sub> content (wt%)	2	10	20	100	200
0%	52	37	32	24	21
2.8%	69	52	48	41	38
7.6%	73	58	53	42	37
15%	82	68	62	49	42

## Vita

Mehul Naginbhai Patel was born in Navsari, India to Naginbhai Gopalbhai and Sudhaben Naginbhai Patel on October 24<sup>th</sup>, 1981. At only six months age, he moved to the United States with his parents. After graduating from the Mississippi School for Mathematics and Science (Columbus, MS) in May, 2000, he entered Vanderbilt University (Nashville, TN). While at Vanderbilt, he conducted undergraduate research with G. Kane Jennings on preparation and characterization of partially fluorinated hexadecanethiol self-assembled monolayers. He graduated with a Bachelor of Engineering degree in Chemical Engineering, *summa cum laude*, in May, 2004. He enrolled at The University of Texas at Austin in August, 2004 for graduate study. Under the supervision of Professor Keith P. Johnston, he earned his Doctor of Philosophy in Chemical Engineering in August, 2009.
